Abstract

We study how changes in the steady-state real interest rate affect the optimal inflation target in a New Keynesian DSGE model with trend inflation and a lower bound on the nominal interest rate. In this setup, a drop in the steady-state real interest rate increases the probability of hitting that constraint. This higher probability can be offset by an increase in the inflation target inducing a higher average nominal interest rate. However, a higher inflation target also entails greater distortion costs induced by steady-state inflation. We estimate the model on both U.S. and euro area data to quantify this trade-off. We find that the relation between the steady-state real interest rate and the optimal inflation target is downward sloping, but its slope is not necessarily one-for-one: increases in the optimal inflation rate are generally lower than declines in the steady-state real interest rate. However, in the currently empirically relevant region for the US as well as the euro area, the slope of the relation is close to -0.9. That latter finding is robust to considering several alternative parameter values as well as parameter uncertainty.

Keywords: inflation target, Effective lower bound.

We thank our discussants Olivier Coibion, Isabel Correia, Kevin Lansing, Argia Sbordone, Raf Wouters, and Johannes Wieland as well as participants at several conferences and seminars, for comments. The views expressed herein are those of the authors and do not necessarily reflect those of the Banque de France or the Eurosystem.
1 Introduction

A recent but sizable literature has pointed to a permanent—or, at least very persistent—decline in the “natural” rate of interest in advanced economies (Del Negro et al., 2018, Holston et al., 2017, Laubach and Williams, 2016). Various likely sources of that decline have been discussed, including a lower trend growth rate of productivity (Gordon, 2015), demographic factors (Eggertsson et al., 2017), or an enhanced preference for safe assets (Caballero and Farhi, 2015, Summers, 2014).

A lower steady-state real interest rate matters for monetary policy. Given average inflation, a lower steady-state real rate will cause the nominal interest rate to hit its zero lower bound (ZLB) more frequently, hampering the ability of monetary policy to stabilize the economy, bringing about more frequent (and potentially protracted) episodes of recessions and below-target inflation.

In the face of that risk, and in order to counteract it, several prominent economists have forcefully argued in favor of raising the inflation target (see, among others, Ball 2014, Blanchard et al. 2010, Williams 2016). Since a lower natural rate of interest is conducive to a higher ZLB incidence, one would expect a higher inflation target to be desirable in that case. But the answer to the practical question of by how much should the target be increased is not obvious. Indeed, the benefit of providing a better hedge against hitting the ZLB, which is an infrequent event, comes at a cost of higher steady-state inflation which induces permanent costs, as recently argued by Bernanke (2016) among others. The answer to this question thus requires to assess how the tradeoff between the incidence of the ZLB and the welfare cost induced by steady-state inflation is modified when the natural rate of interest decreases. While the decrease in the natural rate of interest has been emphasized in the recent literature, such assessment has received surprisingly little attention.

The present paper contributes to this debate by asking two questions. First, to what extent does a lower steady-state real interest rate \( r^\star \) call for a higher optimal inflation target \( \pi^\star \)? Second, does the source of decline in \( r^\star \) matter? Our main contribution is to characterize how the optimal inflation target is related to the steady-state real interest rate, using a structural, empirically estimated, macroeconomic model. Our main findings can be summarized as follows: (i) The relation between \( r^\star \) and \( \pi^\star \) is downward sloping, but not necessarily one-for-one; (ii) in the vicinity of the pre-crisis values for \( r^\star \), the slope of the \((r^\star, \pi^\star)\) locus is close to \(-0.9\); and (iii) for a plausible range of \( r^\star \) values the relation is largely robust to the underlying source of variation in \( r^\star \).

Our results are obtained from extensive simulations of a New Keynesian DSGE model estimated for both the US and the euro area over a Great Moderation sample. The framework features: (i) price stickiness and imperfect indexation of prices to non-zero trend inflation, (ii) wage stickiness and imperfect indexation of wages to both inflation and technical progress, and (iii) a ZLB constraint on the nominal interest rate. The first two features imply the presence of potentially substantial costs associated with non-zero wage or price inflation. The third feature warrants a strictly positive inflation rate, in order to mitigate the incidence
and adverse effects of the ZLB. To our knowledge, these three features have not been jointly taken into account in previous analyses of optimal inflation. Our analysis focuses on the trade-off between the costs attached to the probability of the hitting the ZLB constraint and the costs induced by a positive steady-state inflation rate. In particular one restriction is that our analysis does not incorporate alternative instruments that could be considered by policymakers facing to a change in $r^*$ – such as changing the central bank reaction function, implementing non-conventional policies, or relying on active fiscal policies.

According to our simulations, the pre-crisis optimal inflation target obtained when the policymaker is assumed to know the economy’s parameters with certainty (and taken to correspond to the mode of the posterior distribution) is around 2% for the US and around 1.5% for the euro area (in annual terms). This result is obtained in an environment with a relatively low probability of hitting the ZLB (6% for the US and slightly less than 10% for the euro area), given the small shocks estimated on our Great Moderation sample. Our simulations also show that, a 100 basis point drop of $r^*$ from its pre-crisis level (respectively 2.5% in the US and 2.7% in the euro area) will almost double the probability of hitting the ZLB if the monetary authority keeps its inflation target unchanged. The optimal reaction of the central bank is to increase the inflation target by 99 basis points in the US and by 81 basis points in the euro area. Overall the slope of the $(r^*, \pi^*)$ relation close to -.9 in the vicinity of the pre-crisis parameter region. This optimal reaction mitigates the increase in the probability of hitting the ZLB.

A further noticeable feature of our approach is that we perform a full-blown Bayesian estimation of the model, using both US and euro area data. This allows us not only to assess the uncertainty surrounding $\pi^*$, but also to derive an optimal inflation target taking into account the parameter uncertainty facing the policy maker, including uncertainty with regard to the determinants of the steady-state real interest rate. When that parameter uncertainty is allowed for, the optimal inflation target values increase significantly: 2.40% for the US and 2.20% for the euro area. The reason why the optimal targets under parameter uncertainty are higher has to do with the fact that the loss function is asymmetric so that choosing an inflation target that is lower than the optimal one is more costly than choosing an inflation target that is above. That being said it remains true that a Bayesian-theoretic optimal inflation target rises by about 90 basis points in response to a downward shift of the distribution in $r^*$ of 100 basis points.

We also study the $(r^*, \pi^*)$ relation obtained under a variety of alternative assumptions: a central bank targeting the average realized inflation target instead of an objective inflation goal, a central bank constrained by an effective lower bound on the policy rate that can be below zero, a central bank uncertain about the parameter values of the model but certain about its reaction function, a central bank with a lower or a higher smoothing parameter in the interest-rate policy rule, structural shocks with higher variance, and higher goods and labor market markups. Strikingly, in the empirically relevant region, the slope of the $(r^*, \pi^*)$ curve is much less affected than the level of this locus. It remains in nearly all cases in the same ballpark as in the baseline scenario.

The remaining of the paper is organized as follows. Section 2 presents the New Keynesian model with a
ZLB constraint that is used. Section 3 describes how the model is estimated and simulated, as well as how the welfare-based optimal inflation target is computed. Section 4 is devoted to the analysis of the \((r^*, \pi^*)\) relation. Section 5 discusses this locus for a set of the alternative exercises. Finally Section 6 provides some concluding remarks.

1.1 Related Literature

To our knowledge no paper has systematically investigated the \((r^*, \pi^*)\) relation. Coibion et al. (2012) (and its follow-up Dordal-i-Carreras et al. (2016)) and Kiley and Roberts (2017) are the papers most closely related to ours, as they study optimal inflation in quantitative set-ups that account for the ZLB. However, their analyses hold for a constant steady-state natural rate of interest. Relative to both papers, a key difference is our focus on eliciting the relation between the steady-state real interest rate and optimal inflation. Other differences are (i) our interest in the euro area, in addition to the US; (ii) we estimate, rather than calibrate, the model, and (iii) we allow for wage rigidity in the form of infrequent, staggered, wage adjustments. A distinctive feature with respect to Kiley and Roberts (2017) is that we use a model-consistent, micro-founded loss function to compute optimal inflation.

A series of papers assessed the probability of hitting the ZLB for a given inflation target (see, among others, Chung et al. 2012, Coenen 2003, Coenen et al. 2004). Interestingly, our own assessment of this pre-crisis ZLB incidence falls broadly in the ballpark of available estimates. A related recent contribution by Gust et al. (2017) emphasizes that the ZLB was indeed a significant constraint on monetary policy that exacerbated the recession and inhibited the recovery.\(^1\) Lindé et al. (2017) offer a discussion of alternative methods to implement the ZLB at the estimation stage.

Other relevant references, albeit ones that put little or no emphasis on the ZLB, are the following. An early literature focuses on sticky prices and monetary frictions. In such a context, as shown by Khan et al. (2003) and Schmitt-Grohé and Uribe (2010), the optimal rate of inflation should be slightly negative. Similarly, a negative optimal inflation would result from an environment with trend productivity growth and prices and wages both sticky, as shown by Amano et al. (2009). In this kind of environment, moving from a 2% to a 4% inflation target would be extremely costly, as suggested by Ascari et al. (2015). By contrast, adding search and matching frictions to the setup, Carlsson and Westermark (2016) show that optimal inflation can be positive. Bilbiie et al. (2014) find positive optimal inflation can be an outcome in a sticky-price model with endogenous entry and product variety. Somewhat related, Adam and Weber (2017) show that, even without any ZLB concern, optimal inflation might be positive in the context of a model with heterogeneous firms and systematic firm-level productivity trends. Finally, using a perpetual

\(^1\)Gust et al. (2017) rely on global solution methods while we resort to the lighter algorithms developed by Bodenstein et al. (2009) and Guerrieri and Iacoviello (2015). Given the large set of inflation targets and real interest rates that we need to consider (and given that these have to be considered for each and every parameter configuration in our simulations), a global solution would be computationally prohibitive.
youth model, Lepetit (2017) shows that optimal inflation can be positive in the presence of heterogeneous discount factor, especially when the social planner is more patient than agents.

Among the recent papers with ZLB, Blanco (2016) studies optimal inflation in a state-dependent pricing model, i.e. a “menu cost” model. In this setup, optimal inflation is typically positive. Two forces explain the result. First, as in our analysis, positive inflation edges the economy against detrimental effects of ZLB.\(^2\) Second, as shown by Nakamura et al. (2016), the presence of state-dependent pricing limits considerably the positive relationship between inflation and price dispersion, thus limiting the costs of inflation.

2 The Model

We use a relatively standard medium-scale New Keynesian model as a framework of reference. Crucially, the model features elements that generate a cost to inflation: (1) nominal rigidities, in the form of staggered price and wage setting; (2) less than perfect price (and wage) indexation to past or trend inflation; and (3) trend productivity growth along, to which wages are imperfectly indexed.

As is well known, staggered price setting generates a positive relation between deviations from zero inflation and price dispersion (with the resulting inefficient allocation of resources). Moreover, the lack of indexation to trend magnifies these costs, as emphasized by Ascari and Sbordone (2014). Also, and ceteris paribus, price inflation induces (nominal) wage inflation, which in turn triggers inefficient wage dispersion in the presence of staggered wage setting. Imperfect indexation also magnifies the costs of non-zero price (or wage) inflation as compared to a set-up where price and wages mechanically catch up with trend inflation. Finally the lack of a systematic indexation of wages to productivity also induces an inefficient wage dispersion.

At the same time, there are benefits associated to a positive inflation rate, as interest rates are subject to a ZLB constraint. In particular, and given the steady-state real interest rate, the incidence of binding ZLB episodes should decline with the average rate of inflation. Such episodes hamper the stabilization potential of monetary policy.

Overall, the model we use, and the trade-off between costs and benefits of steady-state inflation, are close to those considered by Coibion et al. (2012). However we assume Calvo-style sticky wages, in addition to sticky prices.\(^3\)

---

\(^2\)By contrast, see Burstein and Hellwig (2008) for a similar exercise without ZLB, which leads to negative optimal inflation rate.

\(^3\)In their robustness analysis, Coibion et al. (2012) consider downward nominal wage rigidity, which entails different mechanisms than with Calvo-style rigidities.
2.1 Households

The economy is inhabited by a continuum of measure one of infinitely-lived, identical households. The representative household is composed of a continuum of workers, each specialized in a particular labor type indexed by \( h \in [0, 1] \). The representative household’s objective is to maximize an intertemporal welfare function

\[
E_t \sum_{s=0}^{\infty} \beta^s \left\{ e^{\xi_{g,t}+} \log(C_{t+s} - \eta C_{t+s-1}) - \frac{\chi}{1 + \nu} \int_0^1 N_{t+s}(h)^{1+\nu} dh \right\},
\]

(1)

where \( \beta \equiv e^{-\rho} \) is the discount factor (\( \rho \) being the discount rate), \( E_t \{ \cdot \} \) is the expectation operator conditional on information available at time \( t \), \( C_t \) is consumption and \( N_t(h) \) is the supply of labor of type \( h \). The utility function features habit formation, with degree of habits \( \eta \). The inverse Frisch elasticity of labor supply is \( \nu \) and \( \chi \) is a scale parameter in the labor disutility. The utility derived from consumption is subject to a preference shock \( \xi_{g,t} \).

The representative household maximizes (1) subject to the sequence of constraints

\[
P_t C_t + e^{\xi_{g,t}+} Q_t B_t \leq \int_0^1 W_t(h) N_t(h) dh + B_{t-1} - T_t + D_t
\]

(2)

where \( P_t \) is the aggregate price level, \( W_t(h) \) is the nominal wage rate associated with labor of type \( h \), \( e^{\xi_{g,t}+} Q_t \) is the price at \( t \) of a one-period nominal bond paying one unit of currency in the next period, where \( \xi_{g,t} \) is a “risk-premium” shock, \( B_t \) is the quantity of such bonds acquired at \( t \), \( T_t \) denotes lump-sum taxes, and \( D_t \) stands for the dividends rebated to the households by monopolistic firms.

2.2 Firms and Price Setting

The final good is produced by perfectly competitive firms according to the Dixit-Stiglitz production function

\[
Y_t = \left( \int_0^1 Y_t(f)^{(\theta_p-1)/\theta_p} df \right)^{\theta_p/(\theta_p-1)},
\]

where \( Y_t \) is the quantity of final good produced at \( t \), \( Y_t(f) \) is the input of intermediate good \( f \), and \( \theta_p \) the elasticity of substitution between any two intermediate goods. The zero-profit condition yields the relation

\[
P_t = \left( \int_0^1 P_t(f)^{1-\theta_p} df \right)^{1/(1-\theta_p)}.
\]

Intermediate goods are produced by monopolistic firms, each specialized in a particular good \( f \in [0, 1] \). Firm \( f \) has technology

\[
Y_t(f) = Z_t L_t(f)^{1/\phi}
\]

where \( L_t(f) \) is the input of aggregate labor, \( 1/\phi \) is the elasticity of production with respect to aggregate labor, and \( Z_t \) is an index of aggregate productivity. The latter evolves according to

\[
Z_t = Z_{t-1} e^{\mu z + \xi_{su}}
\]
where \( \mu_z \) is the average growth rate of productivity. Thus, technology is characterized by a unit root in the model.

Intermediate goods producers are subject to nominal rigidities à la Calvo. Formally, firms face a constant probability \( \alpha_p \) of not being able to re-optimize prices. In the event that firm \( f \) is not drawn to re-optimize at \( t \), it re-scales its price according to the indexation rule

\[
P_t(f) = (\Pi_{t-1})^{\gamma_p} P_{t-1}(f)
\]

where \( \Pi_t \equiv P_t/P_{t-1} \), \( \Pi \) is the associated steady-state value and \( 0 \leq \gamma_p < 1 \). Thus, in case firm \( f \) is not drawn to re-optimize, it mechanically re-scales its price by past inflation. Importantly, however, we assume that the degree of indexation is less than perfect since \( \gamma_p < 1 \). One obvious drawback of the Calvo set-up is that the probability of price change is assumed to be invariant, inter alia to the long run inflation rate. Drawing from the logic of menu cost models, the Calvo parameter of price fixity could be expected to decrease when trend inflation rises. However, in the range of values for trend inflation that we will consider, available micro economic evidence, such as that summarized in Golosov and Lucas (2007), suggests there is no significant correlation between the frequency of price change and trend inflation.

If drawn to re-optimize in period \( t \), a firms chooses \( P_t^* \) in order to maximize

\[
\mathbb{E}_t \sum_{s=0}^{\infty} (\beta \alpha_p)^s \Lambda_{t+s} \left\{ (1 + \tau_{p,t+s}) \frac{V_{t,t+s}^p P_t^*}{P_{t+s}} Y_{t,t+s} - \frac{W_{t+s}}{P_{t+s}} \left( \frac{Y_{t,t+s}}{Z_{t+s}} \right)^\phi \right\},
\]

where \( \Lambda_t \) denotes the marginal utility of wealth, \( \tau_{p,t} \) is a sales subsidy paid to firms and financed via a lump-sum tax on households, and \( Y_{t,t+s} \) is the demand function that a monopolist who last revised its price at \( t \) faces at \( t + s \); it obeys

\[
Y_{t,t+s} = \left( \frac{V_{t,t+s}^p P_t^*}{P_{t+s}} \right)^{-\theta_p} Y_{t+s}
\]

where \( V_{t,t+s}^p \) reflects the compounded effects of price indexation to past inflation

\[
V_{t,t+s}^p = \prod_{j=t}^{t+s-1} (\Pi_j)^{\gamma_p}.
\]

We further assume that

\[
1 + \tau_{p,t} = (1 + \tau_p) e^{-\zeta_{u,t}},
\]

with \( \zeta_{u,t} \) appearing in the system as a cost-push shock. Furthermore, we set \( \tau_p \) so as to neutralize the steady-state distortion induced by price markups.
2.3 Aggregate Labor and Wage Setting

There is a continuum of perfectly competitive labor aggregating firms that mix the specialized labor types according to the CES technology

\[ N_t = \left( \int_0^1 N_t(h)^{(\theta_w - 1)/\theta_w} \, dh \right)^{\theta_w/(\theta_w - 1)}, \]

where \( N_t \) is the quantity of aggregate labor and \( N_t(h) \) is the input of labor of type \( h \), and where \( \theta_w \) denotes the elasticity of substitution between any two labor types. Aggregate labor \( N_t \) is then used as an input in the production of intermediate goods. Equilibrium in the labor market thus requires

\[ N_t = \int_0^1 L_t(f) \, df. \]

Here, it is important to notice the difference between \( L_t(f) \), the demand for aggregate labor emanating from firm \( f \), and \( N_t(h) \), the supply of labor of type \( h \) by the representative household.

The zero-profit condition yields the relation

\[ W_t = \left( \int_0^1 W_t(h)^{1 - \theta_w} \, dh \right)^{1/(1 - \theta_w)}, \]

where \( W_t \) is the nominal wage paid to aggregate labor while \( W_t(h) \) is the nominal wage paid to labor of type \( h \).

Mirroring prices, we assume that wages are subject to nominal rigidities, à la Calvo, in the manner of Erceg et al. (2000). Formally, unions face a constant probability \( \alpha_w \) of not being able to re-optimize wages. In the event that union \( h \) is not drawn to re-optimize at \( t \), it re-scales its wage according to the indexation rule

\[ W_t(h) = e^{\gamma_w \Pi_{t-1}} W_{t-1}(h) \]

where, as before, wages are indexed to past inflation. However, we assume that the degree of indexation is here too less than perfect by imposing \( 0 \leq \gamma_w < 1 \). In addition, nominal wages are also indexed to average productivity growth with indexation degree \( 0 \leq \gamma_z < 1 \).

If drawn to re-optimize in period \( t \), a union chooses \( W_t^* \) in order to maximize

\[ \mathbb{E}_t \sum_{s=0}^{\infty} (\beta \rho_w)^s \left\{ (1 + \tau_w) \Lambda_{t+s} \frac{V_{f,t+s} W_t^*}{P_{t+s}} N_{t,t+s} - \frac{\chi}{1 + \nu} N_{1,t+s} \right\} \]

where the demand function at \( t + s \) facing a union who last revised its wage at \( t \) obeys

\[ N_{t,t+s} = \left( \frac{V_{f,t+s}^w W_t^*}{W_{t+s}} \right)^{-\theta_w} N_{t+s} \]

and where \( V_{f,t+s} \) reflects the compounded effects of wage indexation to past inflation and average productivity growth

\[ V_{f,t+s}^w = e^{\gamma_w \Pi_{t+s} \prod_{j=t}^{t+s-1} (\Pi_j)} \gamma_w. \]

Furthermore, we set \( \tau_w \) so as to neutralize the steady-state distortion induced by wage markups.
2.4 Monetary Policy and the ZLB

Monetary policy in "normal times" is assumed to be given by an inertial Taylor-like interest rate rule

\[ \hat{i}_t = \rho \hat{i}_{t-1} + (1 - \rho_i) \left( a_\pi \hat{\pi}_t + a_y \hat{x}_t \right) + \zeta_{R,t} \]  

(3)

where \( \hat{i}_t \equiv -\log(Q_t) \), with \( \hat{i}_t \) denoting the associated deviation from steady state i.e., \( \hat{i}_t \equiv i_t - i \). Also, \( \pi_t \equiv \log(\Pi_t) \), \( \hat{\pi}_t \equiv \pi_t - \pi \) is the gap between inflation and its target, and \( \hat{x}_t \equiv \log(Y_t/Y^\text{n}_t) \) where \( Y^\text{n}_t \) is the natural level of output, defined as the level of output that would prevail in an economy with flexible prices and wages and no cost-push shocks. Finally, \( \zeta_{R,t} \) is a monetary policy shock.

Here, \( \pi \) should be interpreted as the central bank target for change in the price index. An annual inflation target of 2% would thus imply \( \pi = 2/400 = 0.005 \) as the model will be parameterized and estimated with quarterly data. Note that the inflation target thus defined may differ from average inflation.

Crucially for our purpose, the nominal interest rate \( i_t \) is subject to a ZLB constraint:

\[ i_t \geq 0 \]

The steady-state level of the real interest rate is defined by \( r^* \equiv i - \pi \). Given logarithmic utility, it is related to technology and preference parameters according to \( r^* = \rho + \mu_z \). Combining these elements, it is convenient to write the ZLB constraint in terms the deviation of the nominal interest rate

\[ \hat{i}_t \geq -(\mu_z + \rho + \pi) \]  

(4)

The rule effectively implemented is given by:

\[ \hat{i}_t^n = \rho \hat{i}_{t-1}^n + (1 - \rho_i) \left( a_\pi \hat{\pi}_t + a_y \hat{x}_t \right) + \zeta_{R,t} \]  

(5)

\[ \hat{i}_t = \max\{\hat{i}_t^n, -(\mu_z + \rho + \pi)\} \]  

(6)

An important feature is that - as in Coibion et al. (2012) and in a large share of the recent literature - the lagged rate that matters is the lagged notional interest rate \( \hat{i}_t \), rather than the lagged actual rate.

Before proceeding, several remarks are in order. First, the inflation target, \( \pi \), is not assumed to be optimal. Note also that realized inflation might be on average below the target as a consequence of ZLB episodes, i.e. \( \mathbb{E}\{\pi_t\} < \pi \). In such instances of ZLB, monetary policy fails to deliver the appropriate degree of accommodation, resulting in a more severe recession and lower inflation than in an economy in which there would not be a ZLB constraint.\(^4\) Second, we assume the central bank policy is characterized by a monetary policy rule rather than a Ramsey-type fully optimal policy of the type studied by e.g. Khan et al.

\(^4\)For convenience, Table A.1 in the Appendix summarizes the various notions of optimal inflation and long-run or target inflation considered in this paper.
(2003) or Schmitt-Grohé and Uribe (2010). Such rules have been shown to be a good empirical characterization of the behavior of central banks in the last decades. From an institutional point of view, the setting the inflation objective (or a definition of price stability) appears to be done at a lower frequency than defining the rule operating the interest rate on a day-to-day basis. Note also that two features in our set-up, the inertia in the monetary policy rule, as well as the use of a lagged notionnal rate rather than lagged actual rate, render the policy more persistent and thus closer to a Ramsey-like fully optimal interest rate rule. In particular the dependence of the lagged notionnal rate \( \hat{r}_t \) results in the nominal interest rate \( \hat{i}_t \) being “lower for longer” in the aftermath of ZLB episodes (as \( \hat{r}_t \) will stay negative for a protracted period).

As equation (4) makes clear, \( \mu_z, \rho, \pi \) have symmetric roles in the ZLB constraint. Put another way, for given structural parameters and a given process for \( \hat{i}_t \), the probability of hitting the ZLB would remain unchanged if productivity growth or the discount rate decline by one percent and the inflation target is increased by a commensurate amount at the same time. Based on these observations, one may be tempted to argue that in response to a permanent decline in \( \mu_z \) or \( \rho \), the optimal inflation target \( \pi^* \) will change by the same amount (with a negative sign).

The previous conjecture is, however, incorrect. The reasons for this are twofold. First, any change in \( \mu_z \) (or \( \rho \)) also translates into a change in the coefficients of the equilibrium dynamic system. It turns out that this effect is non-negligible since, as we show later, after a one percentage point decline in \( r^* \) the inflation target has to be raised by more than one percent in order to keep the probability of hitting the ZLB unchanged. Second, because there are welfare costs associated with increasing the inflation target, the policy maker would also have to balance the benefits of keeping the incidence of ZLB episodes constant with the additional costs in terms of extra price dispersion and inefficient resource allocation. These costs can be substantial and more than compensate for the benefits of holding the probability of ZLB constant. Assessing these forces is precisely this paper’s endeavor.

3 Estimation and simulations

3.1 Estimation without a lower bound on nominal interest rates

Estimation procedure Because the model has a stochastic trend, we first induce stationarity by dividing trending variables by \( Z_t \). The resulting system is then log-linearized in the neighborhood of its deterministic steady state.\(^5\) We append to the system a set of equations describing the dynamics of the structural shocks, namely

\[
\zeta_{k,t} = \rho_k \zeta_{k,t-1} + \sigma_k \epsilon_{k,t}, \quad \epsilon_{k,t} \sim N(0,1)
\]

for \( k \in \{ R, g, u, q, z \} \).

\(^5\)See the Technical Appendix for further details.
Absent the ZLB constraint, the model can be solved and cast into the usual linear transition and observation equations:

\[ s_t = T(\theta)s_{t-1} + R(\theta)e_t, \quad x_t = M(\theta) + H(\theta)s_t, \]

with \( s_t \) a vector collecting the model’s state variables, \( x_t \) a vector of observable variables and \( e_t \) a vector of innovations to the shock processes \( e_t = (\epsilon_{R,t}, \epsilon_{g,t}, \epsilon_{u,t}, \epsilon_{q,t}, \epsilon_{z,t})' \). The solution coefficients are regrouped in the conformable matrices \( T(\theta), R(\theta), M(\theta), \) and \( H(\theta) \) which depend on the vector of structural parameters \( \theta \).

We estimate the model using data for a pre-crisis period over which the ZLB constraint is not binding. This enables us to use the linear version of the model. The sample of observable variables is \( X_T \equiv \{x_t\}_{t=1}^T \) with

\[ x_t = [\Delta \log(GDP_t), \Delta \log(GDP\text{ Deflator}_t), \Delta \log(Wages_t), \text{Short Term Interest Rate}_t]' \]

where the short term nominal interest rate is the effective Fed Funds Rate for the US and the Euribor 3 months rate for the Euro-Area. We use a sample of quarterly data covering the period 1985Q2-2008Q3. This choice is guided by two objectives. First, this sample strikes a balance between size and the concern of having a homogeneous monetary policy regime over the period considered. In the US case, the sample covers the Volcker and post-Volcker period, arguably one of relative homogeneity of monetary policy. For the euro area, the sample starts approximately when the disinflation policies were simultaneously conducted in the main euro area countries (see Fève et al. 2010) and then covers the single currency period. Here too, this corresponds to a period of relative monetary policy homogeneity. Second, we use a sample that coincides more or less with the so-called Great Moderation. Over the latter, as has been argued in the literature, we expect smaller shocks to hit the economy. In principle, this will lead to a conservative assessment of the effects of the more stringent ZLB constraint due to lower real interest rates.  

The parameters \( \phi, \theta_p, \) and \( \theta_w \) are calibrated prior to estimation. The parameter \( \theta_p \) is set to 6, resulting in a steady-state price markup of 20%. Similarly, the parameter \( \theta_w \) is set to 3, resulting in a wage markup of 50%. These numbers fall into the arguably large ballpark of available values used in the literature. In the robustness section, we investigate the sensitivity of our results to these parameters. The parameter \( \phi \) is set to 1/0.7. Given the assumed subsidy correcting the steady-state price markup distortion, this results in a steady-state labor share of 70%.

We rely on a full-system Bayesian estimation approach to estimate the other model parameters. After having cast the dynamic system in the state-space representation for the set of observable variables, we use the Kalman filter to measure the likelihood of the observed variables. We then form the joint posterior distribution of the structural parameters by combining the likelihood function \( p(X_T|\theta) \) with a joint density characterizing some prior beliefs \( p(\theta) \). The joint posterior distribution thus obeys

\[ p(\theta|X_T) \propto p(X_T|\theta) p(\theta), \]

The data are obtained from the Fred database for the US and from the “Area Wide Model” database of Fagan et al. (2001) and Eurostat national accounts for the Euro Area. In both cases, the GDP is expressed in per capita terms.

</table>

Note: ‘std’ stands for Standard Deviation, ‘Post.’ stands for Posterior, and ‘Low’ and ‘High’ denote the bounds of the 90% probability interval for the posterior distribution.

Given the specification of the model, the joint posterior distribution cannot be recovered analytically but may be computed numerically, using a Monte-Carlo Markov Chain (MCMC) sampling approach. More specifically, we rely on the Metropolis-Hastings algorithm to obtain a random draw of size 1,000,000 from the joint posterior distribution of the parameters.

Estimation results Tables 1 and 2 present the parameter’s postulated priors (type of distribution, mean, and standard error) and estimation results, i.e., the posterior mean and standard deviation, together with the bounds of the 90% probability interval for each parameter.

For the parameters $\pi$, $\mu_z$ and $\rho$, we impose Gaussian prior distributions. The parameters governing the latter are chosen so that the model steady-state values match the mean values of inflation, real per capita GDP growth, and the real interest rate in our US and euro area samples. Other than for these three parameters, we use the same prior distributions for the structural parameters in both the US and the euro area. Our choice of priors are standard. In particular, we use Beta distributions for parameters in $[0, 1]$, Gamma distributions for positive parameters, and Inverse Gamma distributions for the standard error of the structural shocks.

The estimation results suggest several key differences between the US and the euro area.

First, reflecting the growth differential between the US and the euro area over the sample period, we find a higher growth rate $\mu_z$ in the euro area than in the US. Moreover, it turns out that the real interest rate is also higher on average in the euro area than in the US over the sample period. These two effects combine

in such a way that both economies have similar discount rates. This difference in steady-state real interest rates $r^*$ will play an important role later when we assess the level of the optimal inflation target. Second, we find generically higher degrees of indexation to past inflation in the US than in the euro area. This will translate into a higher tolerance for inflation in the US in our subsequent analysis of the optimal inflation target. This is because a higher indexation helps to mitigate the distortions induced by a higher inflation target. Everything else equal, we thus expect a higher optimal inflation target in the US than in the euro area. Third, we obtain broadly similar parameters for the shocks processes. One exception, though, is the so-called risk-premium shock. The unconditional variance of the US shock is somewhat higher than its euro area counterpart.

For the US, most of our estimated parameters are in line with the calibration adopted by Coibion et al. (2012), with important qualifications. First, we obtain a slightly higher degree of price rigidity than theirs (0.67 versus 0.55). Second, our specification of monetary policy is different from theirs. In particular, they allow for two lags of the nominal interest rate in the monetary policy rule while we only have one lag. However, we can compare the overall degree of interest rate smoothing in the two setups. To this end, abstracting from the other elements of the rule, we simply focus on the sum of autoregressive coefficients. It amounts to 0.92 in their calibration while the degree of smoothing in our setup has a mean posterior value of 0.85. While this might not seem to be a striking difference, it is useful to cast these figures in terms of half-life of convergence in the context of autoregressive model of order 1. Our value implies twice as small a half-life than theirs. Third, our monetary policy shock and our shocks to demand have approximately
twice as small an unconditional standard deviation as theirs.

3.2 Computing the Optimal Inflation Target

Simulations with a ZLB constraint The model becomes non-linear when one allows the ZLB constraint to bind. The solution method we implement follows the approach developed by Bodenstein et al. (2009) and Guerrieri and Iacoviello (2015). The approach can be described as follows. There are two regimes: the no-ZLB regime \( k = n \) and the ZLB regime \( k = e \) and the canonical representation of the system in each regime is

\[
E_t\{A^{(k)} s_{t+1} + B^{(k)} \dot{s}_t + C^{(k)} s_{t-1} + D^{(k)} \epsilon_t \} + f^{(k)} = 0
\]

where \( A^{(k)}, B^{(k)}, C^{(k)}, \) and \( D^{(k)} \) are conformable matrices and \( f^{(k)} \) is a vector of constants. In the no-ZLB regime, the vector \( f^{(n)} \) is filled with zeros. In the ZLB regime, the row of \( f^{(e)} \) associated with \( i_t \) is equal to \( \mu_z + \rho + \pi \). Similarly, the rows of the system matrices associated with \( i_t \) in the no-ZLB regime correspond to the coefficients of the Taylor rule while in the ZLB regime, the coefficient associated with \( i_t \) is equal to 1 and all the other coefficients are set to zero.

In each period \( t \), given an initial state vector \( s_{t-1} \) and vector stochastic innovations \( \epsilon_t \), we simulate the model under perfect foresight (i.e., assuming that no further shocks hit the economy) over the next \( N \) periods, for \( N \) sufficiently large. In case this particular draw is not conducive to a ZLB episode, we find \( s_t \) using the linear solution stated above. In contrast, if this draw leads to a ZLB episode, we postulate integers \( N_e < N \) and \( N_x < N \) such that the ZLB is reached at time \( t + N_e \) and left at time \( t + N_x \). In this case, we solve the model by backward induction. We obtain the time varying solution

\[
s_{t+q} = d_{t+q} + \mathcal{T}_{t+q} s_{t+q-1} + \mathcal{R}_{t+q} \epsilon_{t+q}
\]

where, for \( q \in \{N_e, \ldots, N_x - 1\} \)

\[
\mathcal{T}_{t+q} = -\left( A^{(e)} \mathcal{T}_{t+q+1} + B^{(e)} \right)^{-1} C^{(e)}, \quad \mathcal{R}_{t+q} = -\left( A^{(e)} \mathcal{T}_{t+q+1} + B^{(e)} \right)^{-1} D^{(e)},
\]

\[
d_{t+q} = -\left( A^{(e)} \mathcal{T}_{t+q+1} + B^{(e)} \right)^{-1} \left( A^{(e)} d_{t+q+1} + f^{(e)} \right)
\]

and, for \( q \in \{0, \ldots, N_e - 1\} \)

\[
\mathcal{T}_{t+q} = -\left( A^{(n)} \mathcal{T}_{t+q+1} + B^{(n)} \right)^{-1} C^{(n)}, \quad \mathcal{R}_{t+q} = -\left( A^{(n)} \mathcal{T}_{t+q+1} + B^{(n)} \right)^{-1} D^{(n)},
\]

\[
d_{t+q} = -\left( A^{(n)} \mathcal{T}_{t+q+1} + B^{(n)} \right)^{-1} \left( A^{(n)} d_{t+q+1} + f^{(n)} \right),
\]

using \( \mathcal{T}_{t+N_x} = T, \mathcal{R}_{t+N_x} = R, \) and \( d_{t+N_x} \) set to a column filled with zeros as initial conditions of the backward recursion.

We then check that given the obtained solution, the system hits the ZLB at \( t + N_e \) and leaves the ZLB at \( t + N_x \). Otherwise, we shift \( N_e \) and/or \( N_x \) forward or backward by one period and start all over again until
convergence. Once convergence has been reached, we use the resulting matrices to compute \(s_t\) and repeat the process for all the simulation periods.

Our approach is thus similar to the one used by Coibion et al. (2012) in their study of the optimal inflation target in a New Keynesian setup.\(^7\) A shortcoming of this approach is that the agents in the model are not assumed to expect that the ZLB has some probability to bind again in the future, after the exit from (possible) current ZLB episode. This may bias estimates, as explained by in Gust et al. (2017), even when as in our case estimation is performed on a pre-ZLB period. The scope of this concern is however dampened by the fact that in the pre crisis environment there is evidence that even experts severely underestimated the probability of the ZLB occurring, see Chung et al. (2012).

A welfare-based optimal inflation target A second-order approximation of the household expected utility derived from the structural model is used to quantify welfare, in a similar manner as in Woodford (2003).\(^8\) Let \(W(\pi; \theta)\) denote this welfare criterion. This notation emphasizes that welfare depends on the inflation target \(\pi\) together with the rest of the structural parameters \(\theta\). Two cases are considered concerning the latter. In the baseline case the structural parameters \(\theta\) are fixed at reference values and taken to be known with certainty by the policy maker. In an alternative exercise, the policy maker maximizes welfare while recognizing the uncertainty associated with the model’s parameters.

The optimal inflation target associated with a given vector of parameters \(\theta\), \(\pi^*(\theta)\) is approximated via numerical simulations of the model allowing for an occasionally binding ZLB constraint, using the algorithm outlined above.\(^9\) The optimal inflation rate associated to a particular vector of parameters \(\theta\) is then obtained as the one maximizing the welfare function, that is:

\[
\pi^*(\theta) = \arg \max_{\pi} W(\pi; \theta).
\]

Accounting for Parameter Uncertainty The location of the loss function \(W(\pi; \theta)\) evidently depends on the parameter of the economy. As a result of estimation uncertainty around of \(\theta\), \(\pi^*(\theta)\) will be subject to uncertainty. Further, a policy maker may wish take into account uncertainty surrounding \(\theta\) when defining its optimal target. A relevant feature of the welfare functions in our set-up is that in general they will be markedly asymmetric: adopting an inflation target 1 percentage point below the optimal value generates welfare losses larger than setting it 1 percentage point above. As a result, the certainty-equivalence does

\(^7\)In practice we combine the implementation of the Bodenstein et al. (2009) algorithm developed by Coibion et al. (2012) with the solution algorithm and the parser from Dynare. Our implementation is in the spirit of Guerrieri and Iacoviello (2015), resulting in a less user-friendly yet faster suite of programs.

\(^8\)See the Technical Appendix for details.

\(^9\)More precisely, a sample of size \(T = 100000\) of innovations \(\{\epsilon_t\}_{t=1}^T\) is drawn from a Gaussian distribution (we also allow for a burn in sample of 200 points that we later discard). We use these shocks to simulate the model for given parameter vector \(\theta\). The welfare function \(W(\pi; \theta)\) is approximated by replacing expectations with sample averages. The procedure is repeated for each of \(K = 51\) inflation targets on the grid \(\{\pi^{(k)}\}_{k=1}^K\) ranging from \(\pi = 0.5/4\%\) to \(\pi = 5/4\%\) (expressed in quarterly rates). Importantly, we use the exact same sequence of shocks \(\{\epsilon_t\}_{t=1}^T\) in each and every simulation over the inflation grid.
not hold. A policy maker maximizing expected welfare while recognizing the uncertainty, will choose a an inflation target differing from that corresponding to the case where \( \theta \) is set to its expected value, and taken to be known with certainty, as in our baseline analysis.

Formally, the estimated posterior distribution of parameters \( p(\theta | X_T) \) can be exploited to quantify the impact of parameter uncertainty on the optimal inflation target and to compute a “Bayesian-theoretic optimal inflation target”. We define the latter as the inflation target \( \pi^{**} \) which maximizes the expected welfare not only over the realizations of shocks but also over the realizations of parameters\(^{10}\)

\[
\pi^{**} \equiv \arg \max_{\pi} \int_\theta \mathcal{W}(\pi; \theta)p(\theta | X_T) d\theta.
\]

We interpret the spread between the optimal inflation target at the posterior mean \( \bar{\theta} \) and the optimal Bayesian inflation target as a measure of how uncertainty about the parameter value affects optimal inflation. Given the nature of asymmetry in the welfare function, the spread will turn out to be positive: a bayesian policy maker will tend to choose a higher inflation target than a policymaker taking \( \theta \) to be known and equal to its expectation. A larger inflation target indeed acts as a buffer to hedge against particularly detrimental parameter values (either because they lead to more frequent ZLB episodes or because they lead to particularly acute inflation distortions). We define

\[
\text{Spr}(\theta) \equiv \pi^{**} - \pi^*(\theta)
\]

and assess below \( \text{Spr}(\bar{\theta}) \).

### 3.3 Pre-crisis Optimal inflation Targets and Probability of a ZLB Episode

Figures 1a and 1b display the welfare function for the US and the euro area – expressed as losses relative to the maximum social welfare – associated with three natural benchmarks for the parameter vector \( \theta \): the posterior mean (dark blue line), the median (light blue line), and the mode (lighter blue line). For convenience, the peak of each welfare function is identified with a dot of the same color. Also, to facilitate interpretations, the inflation targets are expressed in annualized percentage rates.

As Figure 1a illustrates, the US optimal inflation target is close to 2% and varies between 1.85% and 2.21% depending on which indicator of central tendency (mean, mode, or median) is selected. This range

\(^{10}\)This Bayesian inflation target is recovered from simulating the model under a ZLB constraint using the exact same sequence of shocks \( \{e_t\}_{t=1}^T \) with \( T = 100000 \) as in the previous subsection (together with the same burn-in sample) and combining it with \( N \) draws of parameters \( \{\theta_j\}_{j=1}^N \) from the estimated posterior distribution \( p(\theta | X_T) \), with \( N = 500 \). As in the previous section, the social welfare function \( \mathcal{W}(\pi; \theta) \) is evaluated for each draw of \( \theta \) over a grid inflation targets \( \{\pi^{(k)}\}_{k=1}^K \). The Bayesian welfare criterion is then computed as the average welfare across parameter draws. Here, we start with the same inflation grid as before and then run several passes. In the first pass, we identify the inflation target maximizing the Bayesian welfare criterion. We then set a finer grid of \( K = 51 \) inflation targets around this value. We repeat this process several times with successively finer grids of inflation targets until the identified optimal inflation target proves insensitive to the grid. In this particular exercise, some parameter draws for \( \theta \) lead to convergence failure in the algorithm implementing the ZLB. These draws are discarded.
of values is consistent with the ones of Coibion et al. (2012) even though in the present paper it is derived from an estimated model over a much shorter sample.\footnote{Coibion et al. (2012) calibrate their model on a post-WWII, pre-Great Recession US sample. By contrast, we use a Great Moderation sample.} Importantly, while the larger shocks in Coibion et al. (2012) ceteris paribus induce larger inflation targets, the high degree of interest rate smoothing in their analysis works in the other direction (as documented below in the last section). In the euro area, as figure 1b reports, the optimal inflation target is close to 1.5% and varies between 1.31% and 1.58% across indicators of central tendency. Altogether, these numbers seem roughly consistent with the quantitative inflation targets adopted by the Fed and the ECB, respectively.

To complement on these illustrative results, figures 2a and 2b display the probability of reaching the ZLB as a function of the annualized inflation target (again, with the parameter vector $\theta$ evaluated at the posterior mean, median, and mode). For convenience, the circles in each curve mark the corresponding optimal inflation target.

According to the simulation exercise, $\pi^{**} = 2.40\%$ for the US and $\pi^{**} = 2.20\%$ for the euro area. In both cases, these robust optimal inflation targets are larger than the values obtained with $\theta$ sets at its central tendency. As expected, a Bayesian policy maker chooses a higher inflation target to hedge against particularly harmful states of the world (i.e., parameter draws) where the frequency of hitting the ZLB is high. Noticeably, this inflation buffer is substantially higher in the euro area where $\text{Spr}(\bar{\theta}) = 0.62\%$, while in the US, $\text{Spr}(\bar{\theta}) = 0.19\%$. This occurs in spite of the optimal inflation target being lower in the euro area than in the US when evaluated at the posterior mean of the parameter vector $\bar{\theta}$.\footnote{Figures C.1a and C.1b in Appendix show the posterior distribution of $\pi^*(\theta)$. It is broadly symmetric in the US and shows...}
The probability of hitting the ZLB associated to these positive optimal inflation targets is relatively low. The probabilities of reaching the ZLB is about 6% for the US and about 10% for the euro area. This result, as anticipated above, is the mere reflection of our choice of a Great Moderation sample. At the same time, our model is able to predict a fairly spread out distribution of ZLB episodes durations, with a significant fraction of ZLB episodes lasting more than say five years (see figures in the appendix). Given the existence of a single ZLB episode in the recent history, we do not attempt here to take a stand on what is a relevant distribution of ZLB episodes (see Dordal-i-Carreras et al. (2016) for some investigation in that direction).

4 The Optimal Inflation Target and the Steady State Real Interest Rate

The focus of this section is to investigate how the monetary authority should adjust its optimal inflation target $\pi^*$ in response to changes in the steady-state real interest rate, $r^*$.\footnote{Note our exercise here is different from assessing what would be the optimal response to a time-varying steady state – a specification consistent with econometric work like that of Holston et al. (2017). Our exercise is arguably consistent with “secular stagnation” understood as a permanently lower real rate of interest – while doing without having to assume a unit root process in the real rate of interest.} Intuitively, with a lower $r^*$ the ZLB is bound to bind more often, so one would expect a higher inflation target should be desirable in that case. But the answer to the practical question of by how much should the target be increased is not obvious. Indeed, the benefit of providing a better hedge against hitting the ZLB, which is an infrequent event, comes at a cost of higher steady-state inflation which induces permanent costs, as argued by, e.g., substantial asymmetry in the euro area.

Bernanke (2016).

To start with, we compute the relation linking the optimal inflation target to the steady-state real interest rate, based on simulations of the model and ignoring parameter uncertainty. We show that the link between $\pi^*$ and $r^*$ depends to some extent on the reason underlying a variation in $r^*$, i.e. a change in the discount rate $\rho$ or a change in growth rate of technology $\mu_z$. In our set-up the first scenario roughly captures the “taste for safe asset” and “ageing population” rationale for secular stagnation, while the second one captures the “decline in technological progress” rationale. We also investigate the role of parameter uncertainty and, in particular, uncertainty about $r^*$, in the determination of the Bayesian-theoretic optimal inflation target. Finally, we investigate how the relation between the optimal inflation target and the steady-state real interest rate depends on various features of the monetary policy framework, as well as on the size of shock or on the price and wage mark-ups.

4.1 The baseline $(r^*, \pi^*)$ relation

To characterize the link between $r^*$ and $\pi^*$, the following simulation exercise is conducted. The structural parameter vector $\theta$ is fixed at its posterior mean, $\bar{\theta}$, with the exception of $\mu_z$ and $\rho$. These two parameters are varied – each in turn, keeping the other parameter, $\mu_z$ or $\rho$, fixed at its baseline posterior mean value. For both $\mu_z$ and $\rho$, we consider values on a grid ranging from 0.4% to 10% in annualized percentage terms. The model is then simulated for each possible values of $\mu_z$ or $\rho$ and various values of inflation targets $\pi$ using the procedure as before. The optimal value $\pi^*$ associated to each value of $r^*$ is obtained as the one maximizing the welfare criterion $W(\pi; \theta)$.

We finally obtain two curves. The first one links the optimal inflation target $\pi^*$ to the steady-state real interest rate $r^*$ for various growth rate of technology $\mu_z$: $\pi^*(r^*(\mu_z))$, where the notation $r^*(\mu_z)$ highlights that the steady-state real interest rate varies as $\mu_z$ varies. The second one links the optimal inflation target $\pi^*$ to the steady-state real interest rate $r^*$ for various discount rates $\rho$: $\pi^*(r^*(\rho))$. Here, the notation $r^*(\rho)$ highlights that the steady-state real interest rate varies as $\rho$ varies.

Figures 3a and 3b depict the $(r^*, \pi^*)$ relations thus obtained for the US and the euro area, respectively. The blue dots correspond to the case when the real steady-state interest rate $r^*$ varies with $\mu_z$. The red dots correspond to the case when the real steady-state interest rate $r^*$ varies with $\rho$. For convenience, both the real interest rate and the associated optimal inflation target are expressed in annualized percentage rates. The dashed grey lines indicate the benchmark result corresponding to the optimal inflation target at the

---

14 In particular, we use the same sequence of shocks $\{e_t\}_{t=1}^T$ as used in the computation implemented in the baseline exercises of Section 3.2. Here again, we start from the same grid of inflation targets for all the possible values of $\mu_z$ or $\rho$. Then, for each value of $\mu_z$ or $\rho$, we refine the inflation grid over successive passes until the optimal inflation target associated with a particular value of $\mu_z$ or $\rho$ proves insensitive to the grid.

15 To illustrate the construction of this figure, see Appendix ???. There, we show how two particular points of this curve are derived from the welfare criteria.

16 Figures E.1a, E.1b, E.2a, and E.2b report similar results at the posterior mode and at the posterior median.
As expected the relations in Figures 3a and 3b are decreasing. However, the slope varies with the value of \( r^* \). For both the US and the euro area, the slope is relatively large in absolute value – although smaller than one – for moderate values of \( r^* \) (say below 4 percent). The slope declines in absolute value as \( r^* \) increases: Lowering the inflation target to compensate for an increase in \( r^* \) becomes less and less desirable. This reflects the fact that, as \( r^* \) increases, the probability of hitting the ZLB becomes smaller and smaller. For very large \( r^* \) values, the probability becomes almost zero, as Figures 4a and 4b show.

At some point, the optimal inflation target becomes insensitive to changes in \( r^* \) when the latter originate from changes in the discount rate \( \rho \). In this case, the inflation target stabilizes at a slightly negative value, in order to lower the nominal wage inflation rate required to support positive productivity growth, given the imperfect indexation of nominal wages to productivity. At the steady state, the real wage must grow at a rate of \( \mu_z \). It is optimal to obtain this steady-state growth as the result of a moderate nominal wage increase and a moderate price decrease, rather than the result of a zero price inflation and a consequently larger nominal wage inflation.  

\[ \text{Note: the blue dots correspond to the } (r^*, \pi^*) \text{ locus when } r^* \text{ varies with } \mu_z; \text{ the red dots correspond to the } (r^*, \pi^*) \text{ locus when } r^* \text{ varies with } \rho. \]

\[ \text{17 Figures F.1a and F.1b in Appendix show the relation between } r^* \text{ and the nominal interest rate when the inflation target is set at its optimal value.} \]

\[ \text{18 For very large } r^*, \text{ as a rough approximation, we can ignore the effects of shocks and assume that the ZLB is a zero-mass event. Assuming also a negligible difference between steady-state and efficient outputs and letting } \lambda_p \text{ and } \lambda_d \text{ denote the weights} \]
The previous tension is even more apparent when \( r^* \) varies with \( \mu_z \) since, in this case, the effects of imperfect indexation of wages to productivity are magnified given that a higher \( \mu_z \) calls for a higher growth in the real wage, which is optimally attained through greater price deflation, as well as a higher wage inflation. Notice however that even in this case, the optimal inflation target becomes little sensitive to changes in \( r^* \) for very large values of \( r^* \), typically above 6%, both in the US and the euro area.

For low values of \( r^* \), on the other hand, the slope of the curve is steeper. In particular, in the empirically relevant region, the relation is not far from one-to-one. More precisely, it shows that, starting from the posterior mean estimate of \( \theta \), a 100 basis points decline in \( r^* \) should lead to a +99 basis points increase in \( \pi^* \) in the US and to a +81 basis points increase in the euro area. Importantly, this increase in the optimal inflation target is the same no matter the underlying factor causing the change in \( r^* \): a drop in potential growth, \( \mu_z \), or a decrease in the discount factor, \( \rho \). At the same time, the probability of ZLB evaluated at the optimal inflation rate also increases when the real rate decreases. In the US case, at some point, the speed at which this probability increases slows down, reflecting that the social planner would choose to increase the inflation target to almost compensate for the higher incidence of ZLB episodes. By contrast, in the euro area, the incidence of ZLB seems to increase substantially after a decline in the real interest rate, even at low values of the latter.

To gain insight into this striking difference, Figures 5a and 5b show how the probability of ZLB changes attached to price dispersion and wage dispersion, respectively, in the approximated welfare function, the optimal inflation obeys \( \pi^* \approx -\lambda_w(1-\gamma_z)(1-\gamma_w)/(1-\gamma_p)^2 + \lambda_w(1-\gamma_w)^2]\mu_z \). Given the low values of \( \lambda_w \) resulting from our estimation, it is not surprising that \( \pi^* \) is negative but close to zero. See Amano et al. (2009) for a similar point in the context of a model abstracting from ZLB issues.

**Note:** the blue dots correspond to the \((r^*, \pi^*)\) locus when \( r^* \) varies with \( \mu_z \); the red dots correspond to the \((r^*, \pi^*)\) locus when \( r^* \) varies with \( \rho \).
as a function of $r^\ast$, holding the inflation target constant. We first set the inflation target at its optimal baseline value (i.e., the value computed at the posterior mean, 2.21 for the US and 1.58 for the euro area). This is reported below as the blue dots. Similarly, we also compute an analog relation assuming this time that the inflation target is held constant at the optimal value consistent with a steady-state real interest rate one percentage point lower (thus, inflation is set to 3.20 for the US and 2.39 for the euro area). Here again, the other parameters are set at their posterior mean. This corresponds to the red dots in the figure.

Consider first the blue line. At the level of the real interest rate prevailing before the permanent decline, assuming that the Central Bank sets its target to the associated optimal level, the probability of reaching the ZLB would be slightly below 6% in the US and close to 9% in the euro area. Imagine now that the real interest rates experiences a decline of 100 basis points. Keeping the inflation target at the same level as prior to the shock, the probability of reaching the ZLB would now climb up to approximately 11% in the US and 16% in the euro area. However, the change in the optimal inflation target brings the probability of reaching the ZLB back to approximately 6% in the US and 11% in the euro area. In the euro area, the social planner is willing to tolerate a smaller inflation target than the one that would fully neutralize the effects of the natural rate decline on the probability of hitting the ZLB. By way of contrast, the social planner in the US would almost neutralize this effect. In this sense, the US economy has a greater tolerance for steady-state inflation than the euro area. This is in part a consequence of the different estimates for the degree of indexation of prices to past inflation found at the estimation stage.

Finally we investigate whether the trade-off analyzed above translates into meaningful welfare costs, measured in terms of foregone per-period consumption. Results are reported in Appendix D. It turns out...
that for the US, under sufficiently low $r^\star$ values, agents faced with a 1 pp decline in the real steady-state interest rates would require up to a 1.5% increase in consuption to be as well-off under the former optimal inflation target (i.e. 2.21%) as under the optimal target associated with the lower real interest rate (3.20% in this case). In the euro area, the results are less marked.

4.2 Accounting for Parameter Uncertainty

Next we investigate the impact of parameter uncertainty on the relation between the optimal inflation target and the steady-state real interest rate. Specifically, we want to determine how the Bayesian-theoretic optimal inflation target $\pi^{**}$ reacts to a downward shift in the distribution of the steady-state real interest rate $r^\star$. Assessing how such a change affects $\pi^{**}$ for every value of $r^\star$ is not possible due to the computational cost involved. Such a reaction is thus investigated for a particular scenario: it is assumed that the economy starts from the posterior distribution of parameters $p(\theta|X_T)$ and that, everything else being constant, the mean of $r^\star$ decreases by 100 basis points. Such a 1 percentage point decline is chosen mainly for illustrative purposes. Yet, it is of a comparable order of magnitude, although relatively smaller in absolute value, as recent estimates of the drop of the natural rate after the crisis such as Laubach and Williams (2016) and Holston et al. (2017). The counterfactual exercise considered can therefore be seen as a relatively conservative characterization of the shift in steady-state real interest rate. Figures 6a and 6b depict the counterfactual shift in the distribution of $r^\star$ that is considered for, respectively, the US and the euro area.

The Bayesian-theoretic optimal inflation target corresponding to the counterfactual lower distribution
of \( r^* \) is obtained from a simulation exercise that relies on the same procedure as before.\(^{19}\) Given a draw in the posterior of parameter vector \( \theta \), the value of the steady-state real interest rate is computed using the expression implied by the postulated structural model \( r^*(\theta) = \rho(\theta) + \mu_z(\theta) \). From this particular draw, a counterfactual lower steady-state real interest rate, \( r^*(\theta_{\Delta}) \), is obtained by shifting the long-run growth component of the model \( \mu_z \) downwards by 1 percentage point (in annualised terms). The welfare function \( \mathcal{W}(\pi; \theta_{\Delta}) \) is then evaluated. Since there are no other changes than this shift in the mean value of \( \mu_z \) in the distribution of the structural parameters, we can characterize the counterfactual distribution \( p(\theta_{\Delta}|X_T) \) as a simple transformation of the estimated posterior \( p(\theta|X_T) \). The counterfactual Bayesian-theoretic optimal inflation target is then obtained as

\[
\pi_{\Delta}^* = \arg \max_{\pi} \int_{\theta_{\Delta}} \mathcal{W}(\pi; \theta_{\Delta}) p(\theta_{\Delta}|X_T) d\theta_{\Delta}.
\]

Figures 7a and 7b illustrate the counterfactual change in optimal inflation target obtained when the steady-state real interest rate declines by 100 basis points and its new value stays uncertain. For the US, the simulation exercise returns a value of \( \pi_{\Delta}^{**} = 3.30\% \) i.e. 90 basis points higher than the optimal value under uncertainty obtained with the posterior distribution of parameters obtained on a pre-crisis sample \( \pi_{\Delta}^* = 2.40\% \). For the euro area, \( \pi_{\Delta}^{**} = 3.10\% \), also 90 basis points higher than the optimal value \( \pi_{\Delta}^* = 2.20\% \) obtained with the baseline posterior distribution of parameters.\(^{20}\)

Thus, we see that a monetary authority that is concerned about the uncertainty surrounding the parameters driving the costs and benefits of the inflation target raises the optimal inflation target but does not

\(^{19}\)Again, we use the same sequence of shocks and the same parameter draws as in section 3.2.

\(^{20}\)Figures G.1a and G.1b in Appendix show how the posterior distribution of \( \pi^* \) is shifted after the permanent decline in the mean of \( r^* \).
alter the reaction of this optimal inflation target following a drop in $r^*$: in both cases, a 100 basis points decrease in the steady-state real interest rate calls for a roughly 90 basis point increase in the optimal inflation target in the vicinity of pre-crisis parameter estimates.

4.3 Further Experiments

In the present section we carry out a number of additional exercises related to the optimal adjustment of the inflation target in response to a change in the steady-state real interest rate. The first four exercises examine the implications of four alternative assumptions regarding monetary policy. The fifth exercise looks at the case of large shocks, while the sixth consider alternative calibrations for the price and wage mark-up.

**Average vs Target Inflation**  As emphasized in recent works (see, notably, Hills et al. 2016, Kiley and Roberts 2017), when the probability of hitting the ZLB is non-negligible, realized inflation is on average significantly lower than the inflation rate that the central bank targets in the interest rate rule (and which would correspond to steady-state inflation in the absence of shocks). This results from the fact that anytime the ZLB is binding (which happens recurrently) the central bank effectively loses its ability to stabilize inflation around the target. Knowing this, it may be relevant to assess the central banks outcomes in terms of the effective average realized inflation. In this section, we investigate whether measuring inflation target in this alternative way matter.

To this end, the analysis of the $(r^*, \pi^*)$ relation of section 4.1 is complemented here with the analysis of the relation between $r^*$ and the average realized inflation rate $\mathbb{E}\{\pi_t\}$ obtained when simulating the model for various values of $r^*$ and the associated optimal inflation target $\pi^*$. In the interest of brevity, the calculations are undertaken assuming that changes in average productivity growth $\mu_z$ is the only source of variation in the natural interest rate.

Figures 8a and 8b illustrate the difference between the $(r^*, \pi^*)$ curve (blue dots) and the $(r^*, \mathbb{E}\{\pi_t\})$ curve (red dots) for the US and the euro area. The overall shape of the curve is unchanged. Unsurprisingly, both curves are identical when $r^*$ is high enough. In this case, the ZLB is (almost) not binding and average realized inflation does not differ much from $\pi^*$. A spread between the two emerges for very low values of $r^*$. There, for low values of the natural rate, the ZLB incidence is higher and, as a result, average realized inflation becomes indeed lower than the optimal inflation target. However, that spread remains limited, less than 10 basis points. The reason is that the implied optimal inflation target is sufficiently high to prevent the ZLB from binding too frequently, thus limiting the extent to which average realized inflation and $\pi^*$ can differ.

Unreported simulation results show that the gap between $\pi^*$ and average realized inflation becomes more substantial when the inflation target is below its optimal value. For instance, mean inflation is roughly zero when the central bank adopts a 1% inflation target in an economy where the optimal inflation
A Negative Effective Lower Bound  The recent experience of many advanced economies (including the euro area) points to an effective lower bound (ELB) for the nominal interest rate below zero. For instance, the ECB’s deposit facility rate, which gears the overnight money market rate because of excess liquidity, was set at a negative value of −10 basis points in June 2014 and has been further lowered down to −40 basis points in March 2016.

We use the estimated euro-area model to evaluate the implications of a negative ELB. More precisely, we set the lower bound on the nominal rate $i_t$ so that

$$ i_t \geq e $$

and we set $e$ to −40 basis points (in annual terms) instead of zero. Results are presented in Figure 9. As expected, the $(r^*, \pi^*)$ locus is shifted downwards, though by somewhat less than 40 basis points. Importantly, its slope remains identical to the baseline case: a 100 basis points downward shift in the distribution of $r^*$ calls for a 90 basis points increase in $\pi^*$.

A Known Reaction Function  Here we study the consequences of the (plausible) assumption that the central bank actually knows the coefficients of its interest rate rule with certainty. More specifically we repeat the same simulation exercise as in subsection 4.2 but with parameters $a_\pi$, $a_y$ and $\rho_i$ in the reaction function 3 taken to be known with certainty. In practice we fix these three parameters at their posterior mean, instead of sampling them from their posterior distribution. This is arguably the relevant approach
Figure 9: Optimal inflation with negative ELB – EA

Figure 10a and 10b present, respectively for the US and the euro area, the Bayesian-theoretic optimal inflation targets obtained when simulating the model at the initial posteriors and after a -100 basis points level shift in the posterior distribution of the long-run growth rate \( \mu_z \) and, hence, the steady-state real rate \( r^* \). According to these simulations, the inflation target should initially be \( \pi^{**} = 2.24\% \) in the US and \( \pi^{**} = 2.36\% \) in the euro area. After the counterfactual change in the distribution of \( r^* \) considered, \( \pi^{**} \) should be increased to 3.16\% in the US and to 3.28\% in the euro area, again in the ballpark of a 90 basis points increase in \( \pi^* \) to compensate for the higher probability to hit the ZLB induced by a 100 basis points downward shift in the distribution of \( r^* \).

What if interest rate smoothing is larger (or lower)? Our analysis is conditional on a specific reaction function of the central bank, described in our setup by the set of parameters \( \alpha_\pi \), \( \alpha_y \) and \( \rho_{TR} \). Among these parameters, the smoothing parameter, \( \rho_{TR} \), has a key influence on the probability of being in a ZLB regime. A higher smoothing has two effects in our model. The first effect is -through standard monetary policy rule inertia- to reduce the speed at which interest rates are raised when the economy exits the lower bound regime since the current rate inherits the past values of the effective nominal rate. The second effect comes from the fact that the smoothing applies to the notional rate \( i_n^* \) that would prevail absent the lower bound constraint (see equation 5) while the effective nominal interest rate is the maximum of zero and the notional rate (see equation 6). Thus the interest rate inherits the past negative values of the notional nominal rate.

\[ \text{21In practice, long-run inflation targets are seldom reconsidered while the rotation in monetary policy committees happens at a higher frequency. From this viewpoint, our baseline assumption of uncertainty on all the monetary policy rule parameters is not necessarily unwarranted.} \]
So, a higher smoothing results in maintaining the effective interest rate at zero for an extended period of time beyond that implied by the macroeconomic shocks that initially brought the economy at the zero lower bound constraint. Such a monetary policy strategy introduces history-dependence whereby, in the instance of a ZLB episode, the central bank is committed to keep rates lower for longer. As this reaction function is known to the agents in the model, this commitment to future accommodation, through generating higher expected inflation and output, helps exiting the trap (or even not entering it).

Through both effects, a large higher degree of smoothing thus reinforces the history-dependence of monetary policy, and tends to shorten the length of ZLB episodes and the probability of hitting the ZLB constraint. Everything else equal, one should therefore expect a lower optimal inflation rate for higher values of the smoothing parameters. This property of the model is illustrated in Figures 11a and 11b which depict the \((r^*, \pi^*)\) relation for respectively the US and the euro-area under three possible values of the smoothing parameter \(\rho_{TR}\). The values used under our baseline scenario, i.e. posterior mean estimates, are .85 for the US and .87 for the euro area. We also consider two alternative setups: A higher value of \(\rho_{TR} = .95\) which is close to the persistence of the central bank reaction function in Coibion et al. (2012), and a lower value of \(\rho_{TR} = .8\). These two values are arguably an upper bound of the existing empirical uncertainty on the degree of smoothing, as they stand outside the 90 % probability interval of our posterior parameter estimates.

The effect of a higher interest rate smoothing is to shift downward the \((r^*, \pi^*)\) curve except for high values of \(r^*\) for which the probability of hitting the ZLB is close to zero and the optimal inflation target is slightly negative. Under this strategy, the pre-crisis optimal inflation rate would be close to 0.5% in the
US and in the euro area.\(^{22}\) Conversely, a lower interest rate smoothing shifts the \((r^*, \pi^*)\) curve upward, even for relatively high values of \(r^*\) — because the probability of being in a ZLB regime increases under this strategy. With a lower \(\rho_{TR}\), the pre-crisis optimal inflation rate would be close to 3.5% in the US and 4% in the euro area.

As for the slope of the \((r^*, \pi^*)\) curve, in the empirically relevant region, it is much less affected than the level of this locus. It is however more affected in this exercise, than in other robustness experiments considered above. A very large smoothing parameter, due to its effect outlined above on the probability of ZLB, somewhat alleviates the extend to which an increase in the inflation target is needed. The slope is indeed close to \(-.7\) for the US and \(-.6\) for the euro area in that case. For a strategy associated with a low smoothing parameter, the slope is close to \(-1\) for both the EA and the US, so closer to the benchmark case but in induced a somewhat curve steeper. For large values of \(r^*\), the degree of smoothing is irrelevant.

**What if shocks are larger?** As argued before, the model is estimated using data from the Great Moderation period. One may legitimately argue that the decline in the real interest rate resulting from the secular stagnation has come hand in hand with larger shocks, as the Great Recession suggests. To address this concern, we simulate the model assuming that demand shocks have a standard error 30 percent larger than estimated.

\(^{22}\)This is not inconsistent with the result in Coibion et al. (2012) who report an optimal inflation target of 1.5% under their baseline calibration on US post WWII data. Indeed, the variance of their underlying shocks is higher than in our baseline which is based on a Great-Moderation estimates. As discussed above, a higher variance of shocks induces more frequent ZLB episodes, hence calls for a higher optimal inflation target.
Figure 12: \((r^*, \pi^*)\) relation with larger demand shocks

(a) US

We conduct this exercise assuming that changes in average productivity growth \(\mu_z\) are the only driver of changes in the natural rate. Apart from \(\sigma_q\) and \(\sigma_g\), which are re-scaled, all the other parameters are frozen at their posterior mean. Given this setup, the optimal inflation target is 3.7% in the US and 2.7% in the euro area, as opposed to 2.21% and 1.58% in the baseline, respectively. Also, under the alternative shock configuration, the probability of hitting the ZLB is 5.3% in the US and 10.1% in the euro, as opposed to 5.5% and 9.4% in the baseline, respectively.

Figures 12a and 12b report the \((r^*, \pi^*)\) relation under larger demand shocks (red dots) and compares the outcome with what obtained in the baseline (blues dots).\(^{23}\) Interestingly, the \((r^*, \pi^*)\) locus has essentially the same slope in the low \(r^*\) region. Here again, we find a slope close to -0.9. However, the curve is somewhat steeper in the high \(r^*\) region and shifted up, compared to the baseline scenario. This reflects that under larger demand shocks, even at very high levels of the natural rate, a drop in the latter is conducive to more frequent ZLB episodes. The social planner is then willing to increase the inflation target at a higher pace than in the baseline scenario and generically sets the inflation target at higher levels to hedge the economy against ZLB episodes.

What if mark-ups are lower (or larger)? The optimal level of inflation in our set-up depends on the elasticities of substitution between any two intermediate goods, \(\theta_p\) and between any two labor types \(\theta_w\).

In our calibration, the baseline value for the elasticity of substitution \(\theta_p\) is 6, leading to a price mark-up

\(^{23}\text{We obtain this figure using the same procedure as outlined before. Here again, we run several passes with successively refined inflation grids.}\)
of 20%. While this value is in line with common “textbook” parameterizations (see Galí, 2015), and is close to the baseline value obtained in Hall (2018) and in Christiano et al. (2005). However, there is considerable uncertainty in the empirical literature about the level of mark-ups. For example, some estimates in Basu and Fernald (1997) and Traina (2015) point to possibly much smaller values, while Autor et al. (2017) and De Loecker and Eeckhout (2017) suggest substantially larger figures. To investigate the robustness of our results, we re-do our main simulation exercise, this time setting $\theta_p$ to a value as large as 10 or as low as $\theta_p$ set to 3. These values approximately cover the range of available empirical estimates.

Similarly, for wage mark-up, there is arguably scarcer evidence, and in any case considerable uncertainty around our baseline parameterization, given by $\theta_w$ set to 3. Here again, so as to cover a broad range of plausible estimates, we run alternatives exercises, setting in turn $\theta_w$ to 8 and $\theta_w$ to 1.5. Results are reported in Figures 13a and 13b in the case of robustness with respect to the price markup, and in Figures 14a and 14b with respect to the wage markup.

The main takeaway from these figures is that our key result is by and large preserved. That is, in the empirically relevant region (for levels of $r^*$ lower than, say, 4 percent), the slope of the $\pi^* - r^*$ curve is only very mildly affected when changing the elasticity of substitution of goods or labor types, be it in the US or in the euro area. A close examination reveals, in the low $r^*$ region, the way the $\pi^* - r^*$ curves moves when changing either $\theta_w$ or $\theta_p$ is not similar for the US and the euro area. This result turns out to depend on the degree of indexation (see Appendix for further illustration), but does not bear quantitative consequences.

Another noticeable result of this robustness exercise is that, by contrast, in the region with high steady-state real interest rates (say $r^*$ larger than 5 percent) the value of optimal inflation target, and the slope of
prices (thus leading to a more pronounced deflation). In that case, it is optimal that is, with a larger substitution across labor types, a given nominal wage growth generates dispersion \( \theta \)ing curves is reversed. That is, a larger \( \theta \) mechanism explains why in Figure 13a and 13b optimal inflation is more negative with lower substitution.

Interestingly, when we consider robustness with respect to parameter \( \theta_w \), the ranking of the corresponding curves is reversed. That is, a larger \( \theta_w \) induces a larger inflation target in absolute value. The reason is that, with a larger substitution across labor types, a given nominal wage growth generates dispersion of quantities across types of labor that turns out to be particularly costly. In that case, it is optimal that the burden of adjustment of real wages to growth is borne not by nominal wages, but rather on nominal prices (thus leading to a more pronounced deflation).\(^{24}\)

\(^{24}\) This can be illustrated again in the approximated welfare function, and ignoring the effects of shocks. Then the optimal inflation obeys \( \pi^* \approx - (\lambda_w (1 - \gamma_z) (1 - \gamma_w) / [\lambda_p (1 - \gamma_p)^2 + \lambda_w (1 - \gamma_w)^2]) \mu_z \). Inflation target is a decreasing function of \( \lambda_w \), thus of \( \theta_w \).
5 Summary and conclusion

In this paper, we have assessed how changes in the steady-state natural interest rate translate into changes in the optimal inflation target in a model subject to the ZLB. Our main finding is that, starting from pre-crisis values, a 1% decline in the natural rate should be accommodated by an increase in the optimal inflation target of about 0.9%. For convenience, Table 3 recaps our results. Overall, across the different concepts of optimal inflation considered in this paper, the level of optimal inflation does vary. However it is a very robust finding that the slope of the \((r^*, \pi^*)\) relation is close to -0.9 in the vicinity of the pre-crisis value of steady-state real interest rates both in the US and in the euro-area.

Note: all figures are in annualized percentage rate.

In our analysis, we considered adjusting the inflation target as the only option at the policymaker’s disposal. This is not to say that this is the only option in their choice set. As a matter of fact, recent discussions revolving around monetary policy in the new normal have suggested that the various non-conventional measures used in the aftermath of the Great Recession could feature permanently in policy toolbox. In particular, unconventional monetary policies could represent useful second-best instruments when the ZLB is reached, as advocated by Reifschneider (2016). An alternative would consist in a change of monetary policy strategies, e.g., adopting a price-level targeting strategy as recently advocated by Williams (2016). Beyond monetary policy measures, fiscal policies could also play a significant role, as emphasized by Correia et al. (2013). As a result, the ZLB might be less stringent a constraint in a practical policy context than in our analysis.\(^{25}\) However, the efficacy and the costs of these policies should also be part of the analysis. The complete comparison of these policy trade-offs goes beyond the scope of the present paper.

---

\(^{25}\)See Debortoli et al. (2018) for empirical evidence in favor of this hypothesis.
We have discussed the impact of higher inflation target, abstracting from the transition to a higher inflation target. In the current lowflation environment, increasing the inflation target in reaction to a drop in the steady-state value of the real interest rate might be challenging: because of more frequent ZLB episodes, the realizations of inflation might be on average below the initial inflation target for some time and increasing the inflation target therefore would raise some credibility issues.

Finally, our analysis has also abstracted from forces identified in the literature as warranting a small, positive inflation target, irrespective of ZLB issues, as emphasized in Bernanke et al. (1999). The first is grounded on measurement issues, following the finding from the 1996 Boskin report that the consumer price index did probably over estimate inflation in the US by over 1 percentage point in the early nineties. The second argument is rooted in downward nominal rigidities. In an economy where there are such downward rigidities (e.g. in nominal wages) a positive inflation rate can help "grease the wheel" of the labor market by facilitating relative price adjustments. Symmetrically, we also abstracted from forces calling for lower inflation targets. The most obvious is the so-called Friedman (1969) rule, according to which average inflation should equal to minus the steady state real interest rate, hence be negative, in order to minimize loss of resources or utility and the distortionary wedge between cash and credit goods (e.g. consumption and leisure) induced by a non-zero nominal interest rate. Presumably, all those were taken into account when deciding the current inflation targets. We conjecture that adding these elements to our setup would leave our main conclusions unchanged. A complete assessment is left for future research.

B The distribution of ZLB spells duration

Figure B.1: Distribution of ZLB spells duration at the posterior mean

(a) US

(b) EA

Note: Histograms are based on a simulated sample of 500,000 quarters. For both the US and the euro areas, simulations are carried out assuming in turn that the inflation target is the estimated inflation target; and then that the inflation target is the optimal inflation target obtained using the mean of the posterior density of estimated parameters.
C The distribution of optimal inflation targets

Figure C.1: Posterior Distribution of $\pi^*$ - EA - Benchmark

(a) US

D The welfare cost of inflation

Following a standard approach when assessing alternative policies, we complement our characterization of optimal inflation by providing measures of consumption-equivalent welfare gains/losses of choosing a suboptimal inflation target.

Let $\mathcal{W}(\pi)$ denote welfare under the inflation target $\pi$. It is defined as

$$\mathcal{W}(\pi) = E_0 \sum_{t=0}^{\infty} \beta^t \left[ \log(\hat{C}_t(\pi)) - \eta \hat{C}_{t-1}(\pi)e^{-\xi_{z,t}} \right] - \frac{\chi}{1 + \nu} \int_0^1 N_t(\pi, h)^{1+v} dh + \Psi_0(\mu_z, \xi_z).$$

Importantly, the welfare function is stated in terms of detrended consumption. The term $\Psi_0$ captures the part of welfare that depends exclusively on $\mu_z$ and $\xi_{z,t}$ and is not affected by changes in the inflation target.

Let us now consider a deterministic economy in which labor supply is held constant at the undistorted steady-state level $N_0$ and in which agents consume the constant level of detrended consumption $\hat{C}(\pi)$. We seek to find the $\hat{C}(\pi)$ such that this deterministic economy enjoys the same level of welfare as above. Thus

$$\mathcal{W}(\pi) = E_0 \sum_{t=0}^{\infty} \beta^t \left[ \log (1 - \eta) \hat{C}(\pi) \right] - \frac{\chi}{1 + \nu} N_0^{1+v} + \Psi_0(\mu_z, 0).$$

Direct manipulations thus yield

$$\mathcal{W}(\pi) = \frac{1}{1 - \beta} \left[ \log (1 - \eta) \hat{C}(\pi) \right] - \frac{\chi}{1 + \nu} N_0^{1+v} + \Psi_0(\mu_z, 0).$$
Consider now an economy with $\pi = \pi^*$ and another one with $\pi = \bar{\pi} \neq \pi^*$. Imagine that in the latter, consumer are compensated in consumption units in such a way that they are as well off with $\bar{\pi}$ as with $\pi^*$. Let $1 + \varphi(\pi)$ denote this percentage increase in consumption. Thus $\varphi(\pi)$ is such that

$$ \mathcal{W}(\pi^*) = \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ \log((1 + \varphi)(1 - \eta)\hat{C}(\pi)) - \frac{\chi}{1 + \nu} \hat{N}^1_{n+1} \right] + \Psi_0(\mu_z, 0) $$

$$ = \frac{\log(1 + \varphi(\pi))}{1 - \beta} + \mathcal{W}(\pi) $$

It then follows that

$$ \varphi(\pi) = \exp\{(1 - \beta)[\mathcal{W}(\pi^*) - \mathcal{W}(\pi)]\} - 1. $$

In practice, welfare is approximated to second order.

We compute $\varphi(\pi)$, both in for the US and the euro area, under two alternative steady-state interest rate scenarios. In the first scenario, we set $r^*$ to the baseline estimated value, corresponding to the posterior mean of $\mu_z + \rho$. In the second scenario, we consider a downward shift in $\mu_z$ by one percentage point (in annual terms), resulting in a lower steady-state real rate. The results are reported in Figures D.1a and D.1b. The blue lines show $\varphi(\pi)$ in the first scenario and the red lines show $\varphi(\pi)$ under a lower real interest rate. For ease of interpretation, the dashed, vertical lines indicate the optimal values of inflation under the two alternative interest rate scenarios.

Figure D.1: Welfare cost of inflation at the posterior mean

(a) US

(b) EA

Note: The figure reports the welfare cost of inflation stated as a percentage of steady-state consumption in the optimal setting.

Figures D.1a and D.1b suggest that in the baseline scenario, the welfare cost of raising or lowering the inflation target by one percentage point is relatively mild. However, this conclusion is not robust to a lower real interest rate. As the red line shows, with a one percentage rate lower $r^*$, the welfare cost of inflation is
assymmetric. It would be much costlier to lower the inflation target than to raise it in the neighborhood of the optimal target. In particular, keeping the inflation target unchanged when faced with a one-percentage point decline in $r^*$ give rise to a 1.5% consumption loss in the US.

E Further illustration of the $(r^*, \pi^*)$ relation

E.1 When $\mu_z$ varies

Figure E.1: $(r^*, \pi^*)$ locus when $\mu_z$ varies

(b) EA

Note: the blue dots correspond to the \((r^*, i^*)\) locus when \(r^*\) varies with \(\mu_z\); the red dots correspond to the \((r^*, i^*)\) locus when \(r^*\) varies with \(\rho\).

G Distribution of \(\pi^*\) following a downward shift of the distribution of \(r^*\)

Figure G.1: Counterfactual - US

(a) US

(b) EA

Note: The dashed vertical line indicates the mean value, i.e. \(E_\theta(\pi^*(\theta))\).
H Additional results on the impact of $\theta_p$ and $\theta_w$ on the $(r^*, \pi^*)$ locus

Here we illustrate why depending on the configuration, a larger $\theta_p$ may lead to a larger optimal inflation target (in the US, see figure 14a) or to a lower one (in the EA, see figure 14b).

**Figure H.1:** $(r^*, \pi^*)$ relation with alternative $\theta_p$ and $\gamma_p$

(a) High $\gamma_p$

(b) Low $\gamma_p$

**Note:** the blues dots correspond to the baseline scenario wherein all the structural parameters are set at their posterior mean $\bar{\theta}$. The red dots correspond to the counterfactual simulation with $\theta_p$ set to 10. The green dots correspond to the counterfactual simulation with $\theta_p$ set to 3.

It turns out that there is a subtle interaction between $\theta_p$ and the degree of indexation to past inflation $\gamma_p$ affecting the shape of the $(r^*, \pi^*)$ locus. To document this, we ran additional simulations: (i) low indexation and low $\theta_p$, (ii) low indexation, high $\theta_p$, (iii) high indexation, low $\theta_p$, and (iv) high indexation and high $\theta_p$. To make as clear a point as possible, in the low indexation case, we set $\gamma_p = 0$ and in the high indexation case, we set $\gamma_p = 0.8$. Both are simulated in the case of the euro area.

To begin with, we consider the case of no indexation. See Figure H.1b. With less substitution (say complementary in the polar case), a given “cyclical” price dispersion induced by inflation, leads to smaller output dispersion. This is apparent from the formulas in our appendix, or textbook e.g. chapter 3 in Galí (2015). Thus with low substitution there is smaller welfare loss to inflation. From this, a lower $\theta_p$ would call for an inflation target farther away from zero. This is what happens in figure H.1b.

Now with a large indexation the detrimental effect of inflation on price dispersion is mitigated. In that case, the policymaker is more willing to set an inflation target farther away from zero (see Figure H.1b). In particular, in the region with low $r^*$ the difference between the low and high $\theta_p$ is no more material.
I Model Solution

I.1 Households

I.1.1 First Order Conditions

The associated lagrangian of program (1) under constraint (2) is

\[ L_t = E_t \sum_{s=0}^{\infty} \beta^s \left\{ e^{\xi_t + s} \log(C_{t+s} - \hat{\eta}C_{t+s-1}) - \frac{X}{1+\nu} \int_0^1 e^{\xi_t+h+s} (N_{t+s}(h))^{1+\nu} \, dh \right\} \]

\[ - \frac{\Lambda_{t+s}}{P_{t+s}} \left[ P_{t+s}C_{t+s} + Q_{t+s}B_{t+s}e^{-\xi_{t+s}} + P_{t+s}tax_{t+s} - \int_0^1 W_{t+s}(h)N_{t+s}(h) \, dh - B_{t+s-1} - P_{t+s}div_{t+s} \right] \}, \]

The associated first order condition with respect to bonds is

\[ \frac{\partial L_t}{\partial B_t} = 0 \iff \Lambda_t Q_t e^{-\xi_t} = \beta E_t \left\{ \frac{\Lambda_{t+1}}{\Pi_{t+1}} \right\}, \] (I.1)

and the first-order condition with respect to consumption is

\[ \frac{\partial L_t}{\partial C_t} = 0 \iff \frac{e^{\xi_t}}{C_t - \hat{\eta}C_{t-1}} - \beta \hat{\eta} E_t \left\{ \frac{e^{\xi_{t+1}}}{C_{t+1} - \eta C_t} \right\} = \Lambda_t. \] (I.2)

where \( \Pi_t = \frac{P_t}{P_{t-1}} \) represents the (gross) inflation rate, and

We induce stationarity by normalizing trending variables by the level of technical progress. To this end, we use the subscript \( z \) to refer to a normalized variable. For example, we define

\[ C_{z,t} = \frac{C_t}{Z_t}, \quad \Lambda_{z,t} = \Lambda_t Z_t, \]

where it is recalled that

\[ Z_t = e^{\xi_t} \]

with

\[ z_t = \mu_t + \xi_{t-1} + \xi_{z,t}. \]

We then rewrite the first order condition in terms of the normalized variables. Equation (I.2) thus rewrites

\[ \frac{e^{\xi_t}}{C_{z,t} - \eta C_{z,t-1}e^{-\xi_{z,t}}} - \beta \hat{\eta} E_t \left\{ \frac{e^{\xi_{z,t+1}}}{C_{z,t+1} - \eta C_{z,t}e^{-\xi_{z,t+1}}} \right\} = \Lambda_{z,t}. \] (I.3)

Similarly, equation (I.1) rewrites

\[ \Lambda_{z,t} Q_t e^{-\xi_t} = \beta e^{-\mu_t} E_t \left\{ e^{-\mu_t} \frac{\Lambda_{z,t+1}}{\Pi_t} \right\}, \] (I.4)

where we defined

\[ \eta = \hat{\eta} e^{-\mu_t}. \]
Let us define $i_t \equiv -\log(Q_t)$ and for any generic variable $X_t$

$$x_t \equiv \log(X_t), \quad \dot{x}_t \equiv x_t - x$$

where $x$ is the steady-state value of $x$. Using these definitions, log-linearizing equation (I.3) yields

$$\dot{g}_t + \beta \eta \mathbb{E}_t \{\dot{c}_{t+1}\} - (1 + \beta \eta^2) \dot{c}_t + \eta \dot{c}_{t-1} - \eta (\zeta_{z,t} - \beta \mathbb{E}_t \{\zeta_{z,t+1}\}) = \varphi^{-1} \dot{\lambda}_t$$

(I.5)

where we defined

$$\varphi^{-1} \equiv (1 - \beta \eta)(1 - \eta),$$

$$\dot{g}_t = (1 - \eta) (\zeta_{c,t} - \beta \eta \mathbb{E}_t \{\zeta_{c,t+1}\}).$$

Similarly, log-linearizing equation (I.4) yields

$$\dot{\lambda}_t = i_t + \mathbb{E}_t \{\dot{\lambda}_{t+1} - \dot{\pi}_{t+1} - \zeta_{z,t+1}\} + \zeta_{q,t}.$$  (I.6)

I.2 Firms

Expressing the demand function in normalized terms yields

$$Y_{z,t}(f) = \left( \frac{P_t(f)}{P_t} \right)^{-\theta_p} Y_{z,t}.$$  

In the case of a firm not drawn to re-optimize, this equation specializes to (in log-linear terms)

$$\dot{y}_{t+s}(f) - \dot{y}_{t+s} = \theta_p (\dot{\pi}_{t+s} - \delta^p_{t+s} - \dot{\pi}_t^p(f)).$$  (I.7)

I.2.1 Cost Minimization

The real cost of producing $Y_t(f)$ units of good of $f$ is

$$\frac{W_t}{P_t} L_t(f) = \frac{W_t}{P_t} \left( \frac{Y_t(f)}{Z_t} \right)^{\phi}$$

(I.8)

The associated real marginal cost is thus

$$S_t(f) = \phi \frac{W_t}{P_t Z_t} \left( \frac{Y_t(f)}{Z_t} \right)^{\phi^{-1}}$$

(I.9)

It is useful at this stage to restate the production function in log-linearized terms:

$$\dot{g}_{z,t}(f) = \frac{1}{\phi} \dot{\pi}_t(f)$$

(I.10)
I.2.2 Price Setting of Intermediate Goods: Optimization

Firm $f$ chooses $P_t^*(f)$ in order to maximize
\[
E_t \sum_{s=0}^{\infty} (\beta \alpha_p)^s \Lambda_{t+s} \left\{ \left( 1 + \tau_{p,t+s} \right) \frac{V^p_{t,t+s} P^*_t(f)}{P_{t+s}} Y^*_t(f) - S(Y_{t,t+s}(f)) \right\},
\]
subject to the demand function
\[
Y^*_t(f) = \left( \frac{V^p_{t,t+s} P^*_t(f)}{P_{t+s}} \right)^{-\theta_p} Y_{t+s},
\]
and the cost schedule (I.8), where $\Lambda_t$ is the representative household’s marginal utility of wealth, and $E_t\{\cdot\}$ is the expectation operator conditional on information available as of time $t$. That $\Lambda_t$ appears in the above maximization program reflects the fact that the representative household is the ultimate owner of firm $f$.

The associated first-order condition is
\[
E_t \sum_{s=0}^{\infty} (\beta \alpha_p)^s \Lambda_{t+s} \left\{ \left( 1 + \tau_{p,t+s} \right) \frac{V^p_{t,t+s} P^*_t(f)}{P_{t+s}} Y^*_t - \frac{\mu_p}{1 + \tau_p} e^{\epsilon_{z,t+s}} W_{t+s} \phi \left( \frac{V^p_{t,t+s} P^*_t(f)}{P_{t+s}} \right)^{-\theta_p} \frac{Y^*_t}{Z^*_t} \right\} = 0,
\]
where
\[
\mu_p \equiv \frac{\theta_p}{\theta_p - 1}.
\]

This rewrites
\[
\left( \frac{P^*_t(f)}{P_t} \right)^{1+\theta_p(\phi-1)} = \frac{\mu_p}{1 + \tau_p} \frac{K_{p,t}}{F_{p,t}},
\]
where
\[
K_{p,t} = E_t \sum_{s=0}^{\infty} (\beta \alpha_p)^s \Lambda_{z,t+s} e^{\epsilon_{z,t+s}} W_{z,t+s} \phi \left( \frac{V^p_{t,t+s} P^*_t(f)}{P_{t+s}} \right)^{-\theta_p} Y_{z,t+s},
\]
and
\[
F_{p,t} = E_t \sum_{s=0}^{\infty} (\beta \alpha_p)^s \Lambda_{z,T} \left( \frac{V^p_{t,t+s} P^*_t(f)}{P_{t+s}} \right)^{-\theta_p} Y_{z,t+s},
\]
where $\Pi_{t,t+s} \equiv P_{t+s}/P_t$.

Notice that
\[
K_{p,t} = \phi \Lambda_{z,t} e^{\epsilon_{z,t}} W_{z,t} (Y_{z,t})^\phi + \beta \alpha_p E_t \left( \frac{(\Pi_t)_{\gamma_p}}{\Pi_{t+1}} \right)^{-\phi \theta_p} K_{p,t+1},
\]
and
\[
F_{p,t} = \Lambda_{z,t} Y_{z,t} + \beta \alpha_p E_t \left( \frac{(\Pi_t)_{\gamma_p}}{\Pi_{t+1}} \right)^{1-\theta_p} F_{p,t+1}.
\]

With a slight abuse of notation, we obtain the steady-state relation
\[
\left( \frac{P^*}{P} \right)^{1+\theta_p(\phi-1)} = \frac{\mu_p}{1 + \tau_p} \frac{W_{z,f}^{\phi-1}}{Y^{1-\theta_p}} \frac{1 - \beta \alpha_p (\Pi^{1-\gamma_p})^{(\theta_p-1)}}{1 - \beta \alpha_p (\Pi)^{\phi \theta_p (1-\gamma_p)}}.
\]
Log-linearizing yields
\[
[1 + \theta_p (\phi - 1)](p^*_t - p_t) = \hat{k}_{p,t} - \hat{f}_{p,t}
\]
\[
\hat{k}_{p,t} = (1 - \omega_{K,p}) [\hat{\lambda}_{z,t} + \hat{\omega}_t + \phi_{z,t} + \zeta_{u,t}] + \omega_{K,p} E_t \{\hat{k}_{p,t+1} + \phi_{t}(\hat{\pi}_{t+1} - \gamma_{p}\hat{\pi}_t)\},
\]
and
\[
\hat{f}_{p,t} = (1 - \omega_{F,p}) (\hat{\lambda}_{z,t} + \hat{g}_{z,t}) + \omega_{F,p} E_t \{\hat{f}_{p,t+1} + (\theta_p - 1) (\hat{\pi}_{t+1} - \gamma_{p}\hat{\pi}_t)\}.
\]

where we defined the de-trended real wage
\[
\omega_t \equiv \hat{w}_{z,t} - p_t
\]

\[
\omega_{K,p} \equiv \beta \alpha_p (\Pi)^{(1-\gamma_p)\phi_{t}}
\]
and
\[
\omega_{F,p} \equiv \beta \alpha_p (\Pi)^{(1-\gamma_p)(\theta_p-1)}
\]

Finally, notice that
\[
P_t^{1-\theta_p} = \int_0^1 P_t(f)^{1-\theta_p} df
\]
\[
= (1 - \alpha_p) (P_t^*)^{1-\theta_p} + \alpha_p \int_0^1 [(\Pi_{t-1})^{\gamma_p} P_{t-1}(f)]^{1-\theta_p} df
\]
Thus
\[
1 = (1 - \alpha_p) \left(\frac{P_t^*}{P_t}\right)^{1-\theta_p} + \alpha_p \left[\frac{(\Pi_{t-1})^{\gamma_p}}{\Pi_t}\right]^{1-\theta_p}
\]
The steady-state relation is
\[
\left(\frac{P_t^*}{P_t}\right)^{1-\theta_p} = \frac{1 - \alpha_p (\Pi)^{(1-\gamma_p)(\theta_p-1)}}{1 - \alpha_p}
\]
Log-linearizing this yields
\[
\hat{\beta}_t = \frac{\omega_{F,p}}{\beta - \omega_{F,p}} (\hat{\pi}_t - \gamma_{p}\hat{\pi}_{t-1}).
\]

I.3 Unions

I.3.1 Wage Setting

Union \( h \) sets \( W_t^*(h) \) so as to maximize
\[
E_t \sum_{s=0}^{\infty} (\beta \alpha_w)^s \left\{ (1 + \tau_w) \frac{\Lambda_{t+s}}{P_{t+s}} e^{\gamma_{z}w_{t+s} V_{t,s}^w} W_t^*(h) N_{t,t+s}(h) - \frac{X}{1 + \nu} e^{\gamma_{z}w_{t+s} V_{t,s}^w / W_{t+s}} W_t^*(h) \right\},
\]
where
\[
N_{t,t+s}(h) = \left( \frac{e^{\gamma_{z}w_{t+s} V_{t,s}^w / W_{t+s}} W_t^*(h)}{W_{t+s}} \right)^{-\theta_w} N_{t+s}
\]
The associated first-order condition is

$$\mathbb{E}_t \sum_{s=0}^{\infty} (\beta \alpha_w)^s \left\{ \Lambda_t \frac{W_{t+s}}{P_{t+s}} N_{t+s} \left( \frac{e^{\tau^w \mu_z \Pi_{t,t+s}^w} W_t^* (h)}{\Pi_{t,t+s}^w} \right)^{1-\theta_w} - \frac{\mu_w}{1+\tau_w} e^{h \xi_{t,t+s}} \left( \frac{e^{\tau^w \mu_z \Pi_{t,t+s}^w} W_t^* (h)}{\Pi_{t,t+s}^w} \right)^{-(1+\nu)\beta_w} N_{t+s}^{1+\nu} \right\} = 0$$

where $$\Pi_{t,t+s}^w = W_{t+s}/W_t$$.

Rearranging yields

$$\left( \frac{W_t^* (h)}{W_t} \right)^{1+\theta_w} = \frac{\mu_w}{1+\tau_w} e^{h \xi_{t,t+s}} \left( \frac{W_t^* (h)}{W_t} \right)^{-(1+\nu)\beta_w} N_{t+s}^{1+\nu}$$

where

$$K_{w,t} = \mathbb{E}_t \sum_{s=0}^{\infty} (\beta \alpha_w)^s \left\{ \Lambda_t \frac{W_{t+s}}{P_{t+s}} N_{t+s} \left( \frac{e^{\tau^w \mu_z \Pi_{t,t+s}^w} W_t^* (h)}{\Pi_{t,t+s}^w} \right)^{1-\theta_w} \right\}$$

and

$$F_{w,t} = \mathbb{E}_t \sum_{s=0}^{\infty} (\beta \alpha_w)^s \left\{ \Lambda_t \frac{W_{t+s}}{P_{t+s}} N_{t+s} \left( \frac{e^{\tau^w \mu_z \Pi_{t,t+s}^w} W_t^* (h)}{\Pi_{t,t+s}^w} \right)^{1-\theta_w} \right\}$$

where $$\Pi_{t,t+s}^w = W_{t+s}/W_t$$.

Notice that

$$K_{w,t} = \chi e^{h \xi_{t,t+s}} N_{t+s}^{1+\nu} + \beta \alpha_w \mathbb{E}_t \left\{ \left( \frac{e^{\tau^w \mu_z (\Pi_t)^{\gamma_w}}}{\Pi_{t,t+1}^w} \right)^{-(1+\nu)\beta_w} K_{w,t+1} \right\}$$

and

$$F_{w,t} = \Lambda_{t,t} \frac{W_{t,t+1}}{P_{t,t}} N_{t} + \beta \alpha_w \mathbb{E}_t \left\{ \left( \frac{e^{\tau^w \mu_z (\Pi_t)^{\gamma_w}}}{\Pi_{t,t+1}^w} \right)^{1-\theta_w} F_{w,t+1} \right\}$$

The associated steady-state relations are

$$\left( \frac{W^*}{W} \right)^{1+\theta_w} = \frac{\mu_w}{1+\tau_w} e^{h \xi_{t,t+s}} \left( \frac{W^*}{W} \right)^{-(1+\nu)\beta_w} N_{t+s}^{1+\nu}$$

$$K_w = \frac{\chi N_{t+s}^{1+\nu}}{1 - \beta \alpha_w [e^{(1-\tau_w)\mu_z (\Pi_t)^{1-\gamma_w}}]^{(1+\nu)\beta_w}}$$

$$F_w = \frac{\Lambda \frac{W_{t,t+1}}{P_{t,t}} H}{1 - \beta \alpha_w [e^{(1-\tau_w)\mu_z (\Pi_t)^{1-\gamma_w}}]^{\theta_w-1}}$$

Log-linearizing the above equations finally yields

$$(1+\theta_w) (w_t^* - w_t) = \hat{k}_{w,t} - \hat{f}_{w,t}.$$
\[
\hat{f}_{w,t} = (1 - \omega_{F,w})(\hat{\lambda}_{z,t} + \hat{\omega}_t + \hat{\alpha}_t) + \omega_{F,w} \mathbb{E}_t \{ \hat{f}_{w,t+1} + (\theta_w - 1)(\hat{\pi}_{w,t+1} - \gamma_w \hat{\pi}_t) \},
\]

where we defined
\[
\omega_{K,w} = \beta \alpha_w [e^{(1-\gamma_z)\mu_z(\Pi)(1-\gamma_w)}]^{1+v}\theta_w
\]
\[
\omega_{F,w} = \beta \alpha_w [e^{(1-\gamma_z)\mu_z(\Pi)(1-\gamma_w)}]^{\theta_w-1}
\]

To complete this section, notice that
\[
1 = (1 - \alpha_w) \left( \frac{W^*_t}{W_t} \right)^{1-\theta_w} + \alpha_w \left( e^{\gamma_z \mu_z \left[ \frac{\Pi_{t-1}}{\Pi_{w,t}} \right]} \right)^{1-\theta_w}
\]
and
\[
\omega^*_t - w_t = \frac{\omega_{F,w}}{\beta - \omega_{F,w}} (\hat{\pi}_{w,t} - \gamma_w \hat{\pi}_{t-1}).
\]

### I.4 Market Clearing

The clearing on the labor market implies
\[
N_t = \left( \frac{Y_t}{Z_t} \right)^\phi \int_0^1 \left( \frac{P_t(f)}{P_t} \right)^{-\phi \theta_p} \, df.
\]
Let us define
\[
\Xi_{p,t} = \left( \int_0^1 \left( \frac{P_t(f)}{P_t} \right)^{-\phi \theta_p} \, df \right)^{-1/(\phi \theta_p)},
\]
so that
\[
N_t = (Y_t \Xi_{p,t})^\phi.
\]
Hence, expressed in log-linear terms, this equation reads
\[
\hat{n}_t = \phi (\hat{\gamma}_{z,t} - \theta_p \hat{\xi}_{p,t}).
\]

Notice that
\[
\Xi_{p,t}^{-\phi \theta_p} = (1 - \alpha_p) \left( \frac{P^*_t}{P_t} \right)^{-\phi \theta_p} + \alpha_p \left( \frac{\Pi_{t-1}}{\Pi_t} \right)^{-\phi \theta_p} \Xi_{p,t-1}^{-\phi \theta_p}.
\]
The associated steady-state relation is
\[
\Xi_p^{-\phi \theta_p} = \frac{(1 - \alpha_p)}{1 - \alpha_p (\Pi(1-\gamma_p)\phi \theta_p)} \left( \frac{P^*_t}{P_t} \right)^{-\phi \theta_p}.
\]
Log-linearizing the price dispersion yields
\[
\hat{\xi}_{p,t} = (1 - \omega_{\Xi})(p^*_t - p_t) + \omega_{\Xi} [\hat{\xi}_{p,t-1} - (\hat{\pi}_t - \gamma_p \hat{\pi}_{t-1})]
\]
where we defined
\[
\omega_{\Xi} = \alpha_p (\Pi(1-\gamma_p)\phi \theta_p).
\]
I.5  Natural Rate of Output

The natural rate of output is the level of production that would prevail in an economy without nominal rigidities, i.e. $\alpha_p = \alpha_w = 0$ and without cost-push shocks (i.e., $\zeta_{u,t} = 0$). Under such circumstances, the dynamic system simplifies to

$$\hat{w}_{z,t} + (\phi - 1)\hat{y}_{z,t} = 0,$$

$$\nu\hat{n}_t + \zeta_{h,t} = \hat{\lambda}_{z,t} + \hat{w}_{z,t},$$

$$\hat{n}_t^n = \phi \hat{g}_{z,t},$$

$$\hat{g}_t + \beta \eta E_t\{\hat{g}_{z,t+1}\} - (1 + \beta \eta^2)\hat{g}_{z,t} + \eta \hat{g}_{z,t-1} - \eta(\zeta_{z,t} - \beta E_t\{\zeta_{z,t+1}\}) = \phi^{-1}\hat{\lambda}_{z,t},$$

where the superscript $n$ stands for natural.

Combining these equations yields

$$[\varphi(1 + \beta \eta^2) + \omega]\hat{g}_{z,t} - \varphi \beta \eta E_t\{\hat{g}_{z,t+1}\} - \varphi \eta \hat{g}_{z,t-1} = \varphi \hat{g}_t - \zeta_{h,t} - \varphi \eta \zeta^*_t$$

where we defined

$$\omega \equiv \nu \phi + \phi - 1,$$

and

$$\zeta^*_t = \zeta_{z,t} - \beta E_t\{\zeta_{z,t+1}\}$$

I.6  Working Out the Steady State

The steady state is defined by the following set of equations

$$\frac{1 - \beta \eta}{(1 - \eta)C} = \Lambda_z,$$

$$e^{-i} = \beta e^{-\mu:\Pi^{-1}},$$

$$\left(\frac{P^*}{P}\right)^{1+\theta_p(\phi - 1)} = \frac{\mu_p}{1 + \tau_p} \frac{K_p}{F_p},$$

$$K_p = \frac{\phi \Lambda_z W_p Y^\phi}{1 - \beta \alpha_p (\Pi)^{\phi\gamma_p(1 - \gamma_p)}},$$

47
\[
F_p = \frac{\Lambda_z Y_z}{1 - \beta \alpha_p (\Pi)^{(1-\gamma_p) (\theta_p - 1)}},
\]

\[
\left( \frac{P}{P} \right)^{1-\theta_p} = \frac{1 - \alpha_p (\Pi)^{(1-\gamma_p) (\theta_p - 1)}}{1 - \alpha_p},
\]

\[
\left( \frac{W^*}{W} \right)^{1+\theta_w \nu} = \frac{\mu_w}{1 + \tau_w \Phi_w'},
\]

\[
K_w = \frac{\chi N^{1+\nu}}{1 - \beta \alpha_w [e^{(1-\gamma_z) \mu_z (\Pi)^{(1-\gamma_w)}}]^{1+\nu} \theta_w'},
\]

\[
F_w = \frac{\Lambda_z W_z H}{1 - \beta \alpha_w [e^{(1-\gamma_z) \mu_z (\Pi)^{(1-\gamma_w)}}]^{\theta_w - 1}},
\]

\[
\left( \frac{W^*}{W} \right)^{1-\theta_w} = \frac{1 - \alpha_w [e^{(1-\gamma_z) \mu_z (\Pi)^{(1-\gamma_w)}}]^{\theta_w - 1}}{1 - \alpha_w},
\]

\[
\Pi_w = \Pi e^{\mu_z}
\]

We can solve for \(i\) and \(\Pi_w\) using

\[
\Pi_w = \Pi e^{\mu_z}
\]

\[
1 = \beta e^{-\mu_z} e^i \Pi^{-1},
\]

Standard manipulations yield

\[
\frac{1 - \omega_{K,p}}{1 - \omega_{F,p}} \left( \frac{\beta (1 - \alpha_p)}{\beta - \omega_{F,p}} \right)^{\frac{1+\theta_p (\theta-1)}{\theta_p - 1}} = \frac{\mu_p}{1 + \tau_p \Phi} \frac{W_z}{P} Y_z^{\Phi - 1},
\]

where we used

\[
\omega_{K,p} = \beta \alpha_p (\Pi)^{(1-\gamma_p) \Phi_p}
\]

\[
\omega_{F,p} = \beta \alpha_p (\Pi)^{(1-\gamma_p) (\theta_p - 1)}
\]

Similar manipulations yield

\[
\frac{1 - \omega_{K,w}}{1 - \omega_{F,w}} \left( \frac{\beta (1 - \alpha_w)}{\beta - \omega_{F,w}} \right)^{\frac{1+\theta_w \nu}{\theta_w - 1}} = \frac{\mu_w}{1 + \tau_w \Lambda_z \Phi_w},
\]

where we used

\[
\omega_{K,w} = \beta \alpha_w [e^{(1-\gamma_z) \mu_z (\Pi)^{(1-\gamma_w)}}]^{(1+\nu) \theta_w}
\]
\[ \omega_{F,w} = \beta \alpha_w [e^{(1-\gamma_w)\mu_z (1-\gamma_w)\theta_w - 1}] \]

Combining these conditions yields
\[
\frac{1 - \omega_{K,w}}{1 - \omega_{F,w}} \left( \frac{\beta (1 - \alpha_w)}{\beta - \omega_{F,w}} \right)^{1+\theta_w} \frac{1 - \omega_{K,p}}{1 - \omega_{F,p}} \left( \frac{\beta (1 - \alpha_p)}{\beta - \omega_{F,p}} \right)^{1+\theta_p} = \frac{\mu_w}{1 + \tau_w} + \frac{\mu_p}{1 + \tau_p} \frac{1 - \eta}{1 - \beta \eta} \phi \chi N^\nu Y^\phi \]

Now, recall that
\[ (Y_z \Xi - \theta_p) = N \]

Then, using
\[ \Xi^{-\phi p} = \frac{1 - \alpha_p}{1 - \omega_z} \left( \frac{P^*}{P} \right)^{-\phi p}, \]

and
\[ \left( \frac{P^*}{P} \right)^{-\phi p} = \left( \frac{\beta (1 - \alpha_p)}{\beta - \omega_{F,p}} \right)^{-\phi p} \]

we end up with
\[ N^\nu Y^\phi_z = \left( \frac{1 - \alpha_p}{1 - \omega_z} \left( \frac{\beta (1 - \alpha_p)}{\beta - \omega_{F,p}} \right)^{-\phi p} \right)^{\nu} Y^{(1+\nu)\phi}_z, \]

so that
\[ \Omega = \frac{\mu_w}{1 + \tau_w} + \frac{\mu_p}{1 + \tau_p} \frac{1 - \eta}{1 - \beta \eta} \phi \chi Y^{(1+\nu)\phi}_z, \]

where
\[ \Omega = \frac{1 - \omega_{K,w}}{1 - \omega_{F,w}} \left( \frac{\beta (1 - \alpha_w)}{\beta - \omega_{F,w}} \right)^{1+\theta_w} \frac{1 - \omega_{K,p}}{1 - \omega_{F,p}} \left( \frac{\beta (1 - \alpha_p)}{\beta - \omega_{F,p}} \right)^{1+\theta_p} \frac{1 - \eta}{1 - \beta \eta} \phi \chi Y^{(1+\nu)\phi}_z. \]

We defined the natural rate of output as the level of production that would prevail in an economy without nominal rigidities, i.e. \( \alpha_p = \alpha_w = 0 \). Under such circumstances, the steady-state value of the (normalized) natural rate of output \( y^n \) obeys
\[ 1 = \frac{\mu_w}{1 + \tau_w} + \frac{\mu_p}{1 + \tau_p} \frac{1 - \eta}{1 - \beta \eta} \phi \chi (Y^n)^{\phi (1+\nu)}. \]

It follows that the steady-state distortion due to sticky prices and wages (and less than perfect indexation) is
\[ \left( \frac{Y_z}{Y^n} \right)^{\phi (1+\nu)} = \Omega. \]

### J Welfare

Let us define for any generic variable \( X_t \)
\[ \frac{X_t - X}{X} = \xi_t + \frac{1}{2} \xi_t^2 + \mathcal{O}(||\zeta||^3) \]
\[
\frac{X_t - X^n}{X^n} = \bar{x} t + \frac{1}{2} \bar{x}^2 + \mathcal{O}(||\zeta||^3)
\]

Below, we repeatedly use the following two lemmas:

**Lemma 1.** Let \( g(\cdot) \) be a twice differentiable function and let \( X \) be a stationary random variable. Then

\[
\mathbb{E}\{g(X)\} = g(\mathbb{E}\{X\}) + \frac{1}{2} g''(\mathbb{E}\{X\}) \mathbb{V}\{X\} + \mathcal{O}(||X||^3).
\]

**Lemma 2.** Let \( g(\cdot) \) be a twice differentiable function and let \( x \) be a stationary random variable. Then

\[
\mathbb{V}\{g(X)\} = [g'(\mathbb{E}\{X\})]^2 \mathbb{V}\{X\} + \mathcal{O}(||X||^3).
\]

In the rest of this section, we take a second-order approximation of welfare, where we consider the inflation rate as an expansion parameter. It follows that we consider the welfare effects of non-zero trend inflation only up to second order.

### J.1 Second-Order Approximation of Utility

Consider first the utility derived from consumption. For the sake of notational simplicity, define

\[
U(C_{z,t} - \eta C_{z,t-1} e^{-\zeta_{z,t}}) = \log(C_{z,t} - \eta C_{z,t-1} e^{-\zeta_{z,t}})
\]

We thus obtain

\[
e^{\zeta_{z,t} U(C_{z,t} - \eta C_{z,t-1} e^{-\zeta_{z,t}})} = \frac{1}{1-\eta} \left[ \left( \frac{C_{z,t} - C^n}{C^n_z} \right) - \eta \left( \frac{C_{z,t-1} - C^n}{C^n_z} \right) \right]
- \frac{1}{2} \frac{1}{(1-\eta)} \left( \frac{C_{z,t} - C^n}{C^n_z} \right)^2
+ \eta \left( \frac{C_{z,t} - C^n}{C^n_z} \right) \left( \frac{C_{z,t-1} - C^n}{C^n_z} \right) - \frac{1}{2} \frac{\eta^2}{(1-\eta)} \left( \frac{C_{z,t-1} - C^n}{C^n_z} \right)^2
+ \zeta_{c,t} \left( \frac{C_{z,t} - C^n}{C^n_z} \right) - \eta \zeta_{c,t} \left( \frac{C_{z,t-1} - C^n}{C^n_z} \right) - \frac{\eta}{(1-\eta)} \zeta_{z,t} \left( \frac{C_{z,t} - C^n}{C^n_z} \right) + \frac{\eta}{(1-\eta)} \zeta_{z,t} \left( \frac{C_{z,t-1} - C^n}{C^n_z} \right)
\]

where t.i.p stands for terms independent of policy.

Then, using

\[
\frac{C_{z,t} - C^n}{C^n_z} = \bar{c}_{z,t} + \frac{1}{2} \bar{c}_{z,t}^2 + \mathcal{O}(||\zeta||^3)
\]

we obtain

\[
e^{\zeta_{z,t} U(C_{z,t} - \eta C_{z,t-1} e^{-\zeta_{z,t}})} = \frac{1}{1-\eta} \left[ \bar{c}_{z,t} - \eta \bar{c}_{z,t-1} + \frac{1}{2} (\bar{c}_{z,t} - \eta \bar{c}_{z,t-1}) \right]
- \frac{1}{2} \frac{1}{1-\eta} \bar{c}_{z,t}^2
+ \eta \bar{c}_{z,t} \bar{c}_{z,t-1} - \frac{1}{2} \eta^2 \frac{1}{1-\eta} \bar{c}_{z,t-1}^2
+ \zeta_{c,t} (\bar{c}_{z,t} - \eta \bar{c}_{z,t-1}) - \frac{\eta}{1-\eta} \zeta_{z,t} (\bar{c}_{z,t} - \bar{c}_{z,t-1}) \right] + \text{t.i.p} + \mathcal{O}(||\zeta||^3),
\]

50
Using
\[ q^{-1} = (1 - \beta \eta)(1 - \eta) \]
we obtain
\[
e^{\xi_{t,1}} U(C_{z,t} - \eta C_{z,t-1} e^{-\zeta_{z,t}}) = \frac{1}{1 - \eta} \left[ \bar{y}_{z,t} - \eta \bar{y}_{z,t-1} + \frac{1}{2} \left( \bar{y}_{z,t}^2 - \eta \bar{y}_{z,t-1}^2 \right) \right] - \frac{1}{2} (1 - \beta \eta) \varphi \bar{y}_{z,t}^2 + \eta (1 - \beta \eta) \varphi \bar{y}_{z,t} \bar{y}_{z,t-1} - \frac{1}{2} \eta^2 (1 - \beta \eta) \varphi \bar{y}_{z,t-1}^2 + \zeta_{t,1} \left( \bar{y}_{z,t} - \eta \bar{y}_{z,t-1} \right) - \eta (1 - \beta \eta) \varphi \zeta_{z,t} \left( \bar{y}_{z,t} - \bar{y}_{z,t-1} \right) \right] + \text{t.i.p} + \mathcal{O}(||\zeta||^3),
\]
where we imposed the equilibrium condition on the goods market.

Similarly, taking a second-order approximation of labor disutility in the neighborhood of the natural steady-state \( N^n \) yields
\[
\frac{X}{1 + \nu} e^{\xi_{t,1}} (N_t(h) - N^n)^1+\nu = \chi(N^n)^{1+\nu} \left( \frac{N_t(h) - N^n}{N^n} \right) + \frac{1}{2} \nu (N^n)^{1+\nu} \left( \frac{N_t(h) - N^n}{N^n} \right)^2 + \chi(N^n)^{1+\nu} \left( \frac{N_t(h) - N^n}{N^n} \right) \zeta_{h,t} + \text{t.i.p} + \mathcal{O}(||\zeta||^3).
\]
Now, using
\[
\frac{N_t(h) - N^n}{N^n} = \bar{n}_t(h) + \frac{1}{2} \bar{n}_t(h)^2 + \mathcal{O}(||\zeta||^3)
\]
we get
\[
\frac{X}{1 + \nu} e^{\xi_{t,1}} (N_t(h) - N^n)^1+\nu = \chi(N^n)^{1+\nu} \left[ \bar{n}_t(h) + \frac{1}{2} (1 + \nu) \bar{n}_t(h)^2 + \bar{n}_t(h) \zeta_{h,t} \right] + \text{t.i.p} + \mathcal{O}(||\zeta||^3).
\]
Integrating over the set of labor types, one gets
\[
\int_0^1 \frac{X}{1 + \nu} e^{\xi_{t,1}} (N_t(h))^{1+\nu} dh = \chi(N^n)^{1+\nu} \left[ \mathbb{E}_h \{ \bar{n}_t(h) \} + \frac{1}{2} (1 + \nu) \mathbb{E}_h \{ \bar{n}_t(h)^2 \} + \mathbb{E}_h \{ \bar{n}_t(h) \} \zeta_{h,t} \right] + \text{t.i.p} + \mathcal{O}(||\zeta||^3).
\]
Now, since
\[
\mathbb{V}_h \{ \bar{n}_t(h) \} = \mathbb{E}_h \{ \bar{n}_t(h)^2 \} - \mathbb{E}_h \{ \bar{n}_t(h) \}^2
\]
the above relation rewrites
\[
\int_0^1 \frac{X}{1 + \nu} e^{\xi_{t,1}} (N_t(h))^{1+\nu} dh = \chi(N^n)^{1+\nu} \left[ \mathbb{E}_h \{ \bar{n}_t(h) \} + \frac{1}{2} (1 + \nu) (\mathbb{V}_h \{ \bar{n}_t(h) \} + \mathbb{E}_h \{ \bar{n}_t(h) \}^2) \right] + \mathbb{E}_h \{ \bar{n}_t(h) \} \zeta_{h,t} \right] + \text{t.i.p} + \mathcal{O}(||\zeta||^3).
\]
We need to express \( \mathbb{E}_h \{ \bar{n}_t(h) \} \) and \( \mathbb{V}_h \{ \bar{n}_t(h) \} \) in terms of the aggregate variables. To this end, we first establish a series of results, on which we draw later on.
J.2 Aggregate Labor and Aggregate Output

Notice that
\[
\frac{\theta_w - 1}{\theta_w} \tilde{n}_t = \log \left( \int_0^1 \left( \frac{N_l(h)}{N^n} \right)^{(\theta_w - 1)/\theta_w} \, dh \right).
\]

Then, applying lemma 1, one obtains
\[
\tilde{n}_t = \mathbb{E}_h \{ \tilde{n}_t(h) \} + \frac{1}{2} \frac{\theta_w}{\theta_w - 1} \mathbb{E}_h \left\{ \left( \frac{N_l(h)}{N^n} \right)^{\theta_w - 1} \right\} -2 \mathcal{V}_h \left\{ \left( \frac{N_l(h)}{N^n} \right)^{\theta_w - 1} \right\} + \mathcal{O}(||\xi||^3).
\]

Then, notice that
\[
\mathcal{V}_h \left\{ \left( \frac{N_l(h)}{N^n} \right)^{\theta_w - 1} \right\} = \mathcal{V}_h \left\{ \exp \left( (1 - \theta_w^{-1}) \log \left( \frac{N_l(h)}{N^n} \right) \right) \right\}
\]
so that, by applying lemma 2, one obtains
\[
\mathcal{V}_h \left\{ \left( \frac{N_l(h)}{N^n} \right)^{\theta_w - 1} \right\} = (1 - \theta_w^{-1})^2 \exp \left( (1 - \theta_w^{-1}) \mathbb{E}_h \{ \tilde{n}_t(h) \} \right)^2 \mathcal{V}_h \{ \tilde{n}_t(h) \} + \mathcal{O}(||\xi||^3).
\]

Similarly
\[
\mathbb{E}_h \left\{ \left( \frac{N_l(h)}{N^n} \right)^{\theta_w - 1} \right\} = \mathbb{E}_h \left\{ \exp \left( (1 - \theta_w^{-1}) \tilde{n}_t(h) \right) \right\}
\]
so that, by applying lemma 1 once more, one obtains
\[
\mathbb{E}_h \left\{ \left( \frac{N_l(h)}{N^n} \right)^{\theta_w - 1} \right\} = \exp \left( (1 - \theta_w^{-1}) \mathbb{E}_h \{ \tilde{n}_t(h) \} \right) \left( 1 + \frac{1}{2} (1 - \theta_w^{-1})^2 \mathcal{V}_h \{ \tilde{n}_t(h) \} \right) + \mathcal{O}(||\xi||^3).
\]

Then combining the previous results
\[
\tilde{n}_t = \mathbb{E}_h \{ \tilde{n}_t(h) \} + \frac{1}{2} \frac{1}{1 - \theta_w^{-1}} \frac{(1 - \theta_w^{-1})^2 \mathcal{V}_h \{ \tilde{n}_t(h) \}}{(1 + \frac{1}{2} (1 - \theta_w^{-1})^2 \mathcal{V}_h \{ \tilde{n}_t(h) \})^2} + \mathcal{O}(||\xi||^3).
\]

It is convenient to define
\[
\Delta_{h,t} \equiv \mathcal{V}_h \{ \tilde{n}_t(h) \}
\]
so that finally
\[
\tilde{n}_t = \mathbb{E}_h \{ \tilde{n}_t(h) \} + Q_{0,h} + \frac{1 - \theta_w^{-1}}{2} Q_{1,h} (\Delta_{h,t} - \Delta_n) + \mathcal{O}(||\xi||^3).
\]

where we defined
\[
Q_{0,h} = \frac{1 - \theta_w^{-1} \Delta_n}{\left[ 1 + \frac{1}{2} (1 - \theta_w^{-1})^2 \Delta_n \right]^2}
\]
and
\[
Q_{1,h} = \frac{1 - \frac{1}{2} (1 - \theta_w^{-1})^2 \Delta_n}{\left[ 1 + \frac{1}{2} (1 - \theta_w^{-1})^2 \Delta_n \right]^3}
\]
Applying the same logic on output and defining

\[ \Delta_{y,t} \equiv \nabla f \{ \tilde{y}_t(f) \} \]

one gets

\[ \tilde{y}_{z,t} = \mathbb{E}_f \{ \tilde{y}_{z,t}(f) \} + Q_{0,y} + \frac{1 - \theta_p^{-1}}{2} Q_{1,y} (\Delta_{y,t} - \Delta_y) + O(||\zeta||^3). \]

where we defined

\[ Q_{0,y} = \frac{1 - \theta_p^{-1}}{2} \Delta_y \left[ 1 + \frac{1}{2} (1 - \theta_p^{-1})^2 \Delta_y \right] \]

and

\[ Q_{1,y} = \frac{1 - \frac{1}{2} (1 - \theta_p^{-1})^2 \Delta_y}{\left[ 1 + \frac{1}{2} (1 - \theta_p^{-1})^2 \Delta_y \right]}. \]

Then recall from (??) and from the equilibrium on the market for aggregate labor that

\[ N_t = \int_0^1 L_t(f) df = \int_0^1 Y_{z,t}(f) \phi df \]

which implies

\[ \frac{N_t}{\hat{N}} = \int_0^1 \left( \frac{Y_{z,t}(f)}{Y_n^u} \right) \phi df \]

where we used \( \hat{N} = (Y_n^u) \phi \).

This relation rewrites

\[ \hat{n}_t = \log \left( \int_0^1 \left( \frac{Y_{z,t}(f)}{Y_n^u} \right) \phi df \right) \]

This expression is of the form

\[ \hat{n}_t = \log \left( \mathbb{E}_f \left\{ \left( \frac{Y_{z,t}(f)}{Y_n^u} \right) \phi \right\} \right). \]

Using lemmas 1 and 2, we obtain the following three approximations

\[ \hat{n}_t = \mathbb{E}_f \{ \phi(\tilde{y}_{z,t}(f) - z_t) \} + \frac{1}{2} \nabla f \left\{ \left( \frac{Y_{z,t}(f)}{Y_n^u} \right) \phi \right\}^2 + O(||\zeta||^3), \]

\[ \nabla f \left\{ \left( \frac{Y_{z,t}(f)}{Y_n^u} \right) \phi \right\} = \phi^2 \left[ \exp \left[ \phi \mathbb{E}_f \{ y_{z,t}(f) \} \right] \right]^2 \nabla f \{ \tilde{y}_{z,t}(f) \} + O(||\zeta||^3), \]

\[ \mathbb{E}_f \left\{ \left( \frac{y_{z,t}(f)}{y_n^u} \right) \phi \right\} = \exp \left[ \phi \mathbb{E}_f \{ y_{z,t}(f) \} \right] \left( 1 + \frac{1}{2} \phi^2 \nabla f \{ \tilde{y}_{z,t}(f) \} \right) + O(||\zeta||^3). \]

Combining these expressions as before yields

\[ \hat{n}_t = \phi \mathbb{E}_f \{ y_{z,t}(f) \} + \frac{1}{2} \phi^2 \nabla f \{ \tilde{y}_{z,t}(f) \} \left( 1 + \frac{1}{2} \phi^2 \nabla f \{ \tilde{y}_{z,t}(f) \} \right)^2 + O(||\zeta||^3). \]
We finally obtain
\[ \hat{n}_t = \phi \mathbb{E}_f \{ \hat{y}_{z,t} (f) \} + P_{0,y} + \frac{1}{2} \phi^2 P_{1,y} (\Delta y_t - \Delta y) + O(||\zeta||^3), \]
where we used
\[ \mathcal{V}_f \{ \hat{y}_{z,t} (f) \} = \frac{\Delta y}{(1 + \frac{1}{2} \phi^2 \Delta y)} + \frac{1 - \frac{1}{2} \phi^2 \Delta y}{(1 + \frac{1}{2} \phi^2 \Delta y)} (\Delta y_t - \Delta y) + O(||\zeta||^3) \]
and defined
\[ P_{0,y} = \frac{\frac{1}{2} \phi^2 \Delta y}{(1 + \frac{1}{2} \phi^2 \Delta y)^2} \]
and
\[ P_{1,y} = \frac{1 - \frac{1}{2} \phi^2 \Delta y}{(1 + \frac{1}{2} \phi^2 \Delta y)^3} \]

### J.3 Aggregate Price and Wage Levels

The aggregate price index is
\[ P_t^{1-\theta_p} = \left( \int_0^1 P_t(f)^{1-\theta_p} \, df \right) \]
and the aggregate wage index is
\[ W_t^{1-\theta_w} = \left( \int_0^1 W_t(h)^{1-\theta_w} \, dh \right). \]

From lemma 1 and the definitions of \( P_t \) and \( W_t \), we obtain
\[ p_t = \mathbb{E}_f \{ p_t(f) \} + \frac{1}{2} \frac{1}{1 - \theta_p} \mathcal{V}_f \{ P_t(f)^{1-\theta_p} \} + O(||\zeta||^3), \]
and
\[ w_t = \mathbb{E}_h \{ w_t(h) \} + \frac{1}{2} \frac{1}{1 - \theta_w} \mathcal{V}_h \{ W_t(h)^{1-\theta_w} \} + O(||\zeta||^3). \]

Then, from lemma 2, we obtain
\[ \mathcal{V}_f \{ P_t(f)^{1-\theta_p} \} = \mathcal{V}_f \{ \exp[(1 - \theta_p) p_t(f)] \} \]
\[ = (1 - \theta_p)^2 \exp[(1 - \theta_p) \hat{p}_t]^2 \Delta p_{t,t} + O(||\zeta||^3), \]
and
\[ \mathcal{V}_h \{ W_t(h)^{1-\theta_w} \} = \mathcal{V}_h \{ \exp[(1 - \theta_w) w_t(h)] \} \]
\[ = (1 - \theta_w)^2 \exp[(1 - \theta_w) \hat{w}_t]^2 \Delta w_{t,t} + O(||\zeta||^3), \]
where we defined
\[ \hat{p}_t = \mathbb{E}_f \{ p_t(f) \}, \quad \hat{w}_t = \mathbb{E}_h \{ w_t(h) \}, \]

\[ 54 \]
\[ \Delta_{p,t} = \mathbb{V}_f\{p_t(f)\}, \quad \Delta_{w,t} = \mathbb{V}_h\{w_t(h)\}. \]

Applying lemma 1 once again, we obtain
\[ \mathbb{E}_f\{P_t(f)^{1-\theta_p}\} = \mathbb{E}_f\{\exp[(1-\theta_p)p_t(f)]\} \]
\[ = \exp[(1-\theta_p)p_t] \left( 1 + \frac{1}{2}(1-\theta_p)^2 \Delta_{p,t} \right) \]
and
\[ \mathbb{E}_h\{W_t(h)^{1-\theta_w}\} = \mathbb{E}_h\{\exp[(1-\theta_w)w_t(h)]\} \]
\[ = \exp[(1-\theta_w)w_t] \left( 1 + \frac{1}{2}(1-\theta_w)^2 \Delta_{w,t} \right) \]

Combining these relations, we obtain
\[ p_t = \tilde{p}_t + \frac{1}{2} \frac{(1-\theta_p)\Delta_{p,t}}{[1 + \frac{1}{2}(1-\theta_p)^2 \Delta_{p,t}]^2} + \mathcal{O}(||\zeta||^3), \]
and
\[ w_t = \tilde{w}_t + \frac{1}{2} \frac{(1-\theta_w)\Delta_{w,t}}{[1 + \frac{1}{2}(1-\theta_w)^2 \Delta_{w,t}]^2} + \mathcal{O}(||\zeta||^3). \]

Thus
\[ p_t = \tilde{p}_t + Q_{0,p} + \frac{1-\theta_p}{2} Q_{1,p}(\Delta_{p,t} - \Delta_p) + \mathcal{O}(||\zeta||^3), \]
and
\[ w_t = \tilde{w}_t + Q_{0,w} + \frac{1-\theta_w}{2} Q_{1,w}(\Delta_{w,t} - \Delta_w) + \mathcal{O}(||\zeta||^3). \]

where we defined
\[ Q_{0,p} = \frac{1-\theta_p}{2} \frac{\Delta_p}{[1 + \frac{1}{2}(1-\theta_p)^2 \Delta_p]^2}, \quad Q_{0,w} = \frac{1-\theta_w}{2} \frac{\Delta_w}{[1 + \frac{1}{2}(1-\theta_w)^2 \Delta_w]^2} \]
and
\[ Q_{1,p} = \frac{1 - \frac{1}{2}(1-\theta_p)^2 \Delta_p}{[1 + \frac{1}{2}(1-\theta_p)^2 \Delta_p]^3}, \quad Q_{1,w} = \frac{1 - \frac{1}{2}(1-\theta_w)^2 \Delta_w}{[1 + \frac{1}{2}(1-\theta_w)^2 \Delta_w]^3} \]

Remark that the constant terms in the second-order approximation of the log-price index can be rewritten as
\[ Q_{0,p} - \frac{1-\theta_p}{2} Q_{1,p} \Delta_p = \frac{1}{2} \frac{(1-\theta_p)^3 \Delta_p^2}{[1 + \frac{1}{2}(1-\theta_p)^2 \Delta_p]^3}. \]

Finally, using the demand functions, one obtains
\[ \tilde{g}_{z,t}(f) = -\theta_p [p_t(f) - p_t] + \tilde{g}_{z,t}, \]
\[ \tilde{n}_t(h) = -\theta_w [w_t(h) - w_t] + \tilde{n}_t, \]
from which we deduce that
\[ \Delta_y, t = \theta_p^2 \Delta p, t \]
and
\[ \Delta h, t = \theta_w^2 \Delta w, t. \]

### J.4 Price and Wage Dispersions

We now derive the law of motion of price dispersion. Notice that
\[ \Delta p, t = \mathbb{V}_f \{ p_t(f) - \bar{p}_{t-1} \} \]

Immediate manipulations of the definition of the cross-sectional mean of log-prices yield
\[ \bar{p}_t - \bar{p}_{t-1} = \alpha_p \gamma_p \pi_{t-1} + (1 - \alpha_p) [p^*_t - \bar{p}_{t-1}]. \]  
(J.1)

Then, the classic variance formula yields
\[ \Delta p, t = \mathbb{E}_f \{ [p_t(f) - \bar{p}_{t-1}]^2 \} - [\mathbb{E}_f \{ p_t(f) - \bar{p}_{t-1} \}]^2 \]

Using this, we obtain
\[ \Delta p, t = \alpha_p \mathbb{E}_f \{ [p_{t-1}(f) - \bar{p}_{t-1} + \gamma_p \pi_{t-1}]^2 \} + (1 - \alpha_p) [p^*_t - \bar{p}_{t-1}]^2 - [\bar{p}_t - \bar{p}_{t-1}]^2 \]

Notice that
\[
(1 - \alpha_p) [p^*_t - \bar{p}_{t-1}]^2 - [\bar{p}_t - \bar{p}_{t-1}]^2
\]
\[
= (1 - \alpha_p) \left[ \frac{1}{1 - \alpha_p} (p_t - \bar{p}_{t-1}) - \frac{\alpha_p}{1 - \alpha_p} \gamma_p \pi_t \right]^2 - [\bar{p}_t - \bar{p}_{t-1}]^2
\]
\[
= \frac{\alpha_p}{1 - \alpha_p} [\bar{p}_t - \bar{p}_{t-1} - \gamma_p \pi_t]^2 - \alpha_p [\gamma_p \pi_t]^2
\]

Using this in the above equation yields
\[ \Delta p, t = \alpha_p \mathbb{E}_f \{ [p_{t-1}(f) - \bar{p}_{t-1} + \gamma_p \pi_{t}]^2 \} - \alpha_p [\gamma_p \pi_{t}]^2 + \frac{\alpha_p}{1 - \alpha_p} [\bar{p}_t - \bar{p}_{t-1} - \gamma_p \pi_t]^2 \]

Now, notice also that
\[ \alpha_p \mathbb{E}_f \{ [p_{t-1}(f) - \bar{p}_{t-1}]^2 \} = \alpha_p \mathbb{E}_f \{ [p_{t-1}(f) - \bar{p}_{t-1} + \gamma_p \pi_{t}]^2 \} - \alpha_p [\gamma_p \pi_{t}]^2 \]

It then follows that
\[ \Delta p, t = \alpha_p \mathbb{E}_f \{ [p_{t-1}(f) - \bar{p}_{t-1}]^2 \} + \frac{\alpha_p}{1 - \alpha_p} [\bar{p}_t - \bar{p}_{t-1} - \gamma_p \pi_t]^2 \]
Hence
\[ \Delta_{p,t} = \alpha_p \Delta_{p,t-1} + \frac{\alpha_p}{1 - \alpha_p} [\bar{p}_t - \bar{p}_{t-1} - \gamma_p \tau_t]^2 \]

Using
\[ p_t = \bar{p}_t + Q_{0,p} + \frac{1 - \theta_p}{2} Q_{1,p} (\Delta_{p,t} - \Delta_p) + O(||\xi||^3), \]
we obtain
\[ \bar{p}_t - \bar{p}_{t-1} = \pi_t - \frac{1 - \theta_p}{2} Q_{1,p} (\Delta_{p,t} - \Delta_{p,t-1}) + O(||\xi||^3). \]
Hence
\[ \Delta_{p,t} = \alpha_p \Delta_{p,t-1} + \frac{\alpha_p}{1 - \alpha_p} \left[ \pi_t - \frac{1 - \theta_p}{2} Q_{1,p} (\Delta_{p,t} - \Delta_{p,t-1}) - \gamma_p \pi_{t-1} \right]^2 + O(||\xi||^3). \]

The steady-state value of \( \Delta_p \) is thus
\[ \Delta_p = \frac{(1 - \gamma_p)^2 \alpha_p}{(1 - \alpha_p)^2} \pi^2 \]

We obtain finally
\[ \Delta_{p,t} = \alpha_p \Delta_{p,t-1} + \frac{\alpha_p}{1 - \alpha_p} \left[ (1 - \gamma_p) \pi_t + \pi_t - \gamma_p \pi_{t-1} - \frac{1 - \theta_p}{2} Q_{1,p} (\Delta_{p,t} - \Delta_{p,t-1}) \right]^2 + O(||\xi||^3). \]

Unless \( \pi \) is itself treated as an expansion variable in the above approximation, we cannot claim that \( \Delta_{p,t} \) is second-order.

We now derive the law of motion of wage dispersion. Following similar steps as for price dispersion, notice that
\[ \Delta_{w,t} = \Psi_h \{ \bar{w}_t(h) - \bar{w}_{t-1} \} \]

Immediate manipulations of the definition of the cross-sectional mean of log-wages yield
\[ \bar{w}_t - \bar{w}_{t-1} = \alpha_w (\gamma_z \mu_z + \gamma_w \pi_{t-1}) + (1 - \alpha_w) [w_t^* - \bar{w}_{t-1}]. \] (J.2)

Then, the classic variance formula yields
\[ \Delta_{w,t} = E_h \left\{ [w_t(h) - \bar{w}_{t-1}]^2 \right\} - \left\{ E_h \{ \bar{w}_t(h) - \bar{w}_{t-1} \} \right\}^2 \]

Using this, we obtain
\[ \Delta_{w,t} = \alpha_w E_h \{ [w_{t-1}(h) - \bar{w}_{t-1} + \gamma_z \mu_z + \gamma_w \pi_{t-1}]^2 \} + (1 - \alpha_w) [w_t^* - \bar{w}_{t-1}]^2 - [\bar{w}_t - \bar{w}_{t-1}]^2 \]

Notice that
\[ w_t^* - \bar{w}_{t-1} = \frac{1}{1 - \alpha_w} (\bar{w}_t - \bar{w}_{t-1}) - \frac{\alpha_w}{1 - \alpha_w} [\gamma_z \mu_z + \gamma_w \pi_t] \]
so that

\[
(1 - \alpha_w)[w^*_t - \bar{w}_{t-1}]^2 - [\bar{w}_t - \bar{w}_{t-1}]^2
\]

\[
= (1 - \alpha_w)\left[\frac{1}{1 - \alpha_w}(\bar{w}_t - \bar{w}_{t-1}) - \frac{\alpha_w}{1 - \alpha_w} [\gamma_z \mu_z + \gamma_w \tau_t]\right]^2 - [\bar{w}_t - \bar{w}_{t-1}]^2
\]

\[
= \frac{\alpha_w}{1 - \alpha_w} [\bar{w}_t - \bar{w}_{t-1} - [\gamma_z \mu_z + \gamma_w \tau_t]^2 - \alpha_w \gamma_z \mu_z + \gamma_w \tau_t]^2
\]

Using this in the above equation yields

\[
\Delta_{w,t} = \alpha_w \mathbb{E}_h \{ [w_{t-1}(h) - \bar{w}_{t-1} + \gamma_z \mu_z + \gamma_w \tau_t]^2 \}
\]

\[
- \alpha_w [\gamma_w \log(1 + \tau_t)]^2 + \frac{\alpha_w}{1 - \alpha_w} [\bar{w}_t - \bar{w}_{t-1} - [\gamma_z \mu_z + \gamma_w \tau_t]^2]
\]

Now, notice also that

\[
\alpha_w \mathbb{E}_h \{ [w_{t-1}(h) - \bar{w}_{t-1}]^2 \} = \alpha_w \mathbb{E}_h \{ [w_{t-1}(h) - \bar{w}_{t-1} + \gamma_z \mu_z + \gamma_w \tau_t]^2 \} - \alpha_w \gamma_z \mu_z + \gamma_w \tau_t]^2
\]

It then follows that

\[
\Delta_{w,t} = \alpha_w \Delta_{w,t-1} + \frac{\alpha_w}{1 - \alpha_w} [\bar{w}_t - \bar{w}_{t-1} - [\gamma_z \mu_z + \gamma_w \tau_t]^2]
\]

Hence

\[
\Delta_{w,t} = \alpha_w \Delta_{w,t-1} + \frac{\alpha_w}{1 - \alpha_w} [\bar{w}_t - \bar{w}_{t-1} - [\gamma_z \mu_z + \gamma_w \tau_t]^2]
\]

which, in turn, implies

\[
\Delta_{w,t} = \alpha_w \Delta_{w,t-1} + \frac{\alpha_w}{1 - \alpha_w} [\bar{w}_t - \bar{w}_{t-1} - [\gamma_z \mu_z + \gamma_w \tau_t - \gamma_z \mu_z + \gamma_w \tau_{t-1}]^2
\]

Using

\[
w_t = \bar{w}_t + Q_{0,w} + \frac{1 - \theta_w}{2} Q_{1,w}(\Delta_{w,t} - \Delta_w) + \mathcal{O}(||\xi||^3),
\]

we obtain

\[
\bar{w}_t - \bar{w}_{t-1} = \pi_{w,t} - \frac{1 - \theta_w}{2} Q_{1,w}(\Delta_{w,t} - \Delta_{w,t-1}) + \mathcal{O}(||\xi||^3).
\]

Hence

\[
\Delta_{w,t} = \frac{\alpha_w}{1 - \alpha_w} \left[\pi_{w,t} - \frac{1 - \theta_w}{2} Q_{1,w}(\Delta_{w,t} - \Delta_{w,t-1})
\]

\[
- \gamma_z \mu_z - \gamma_w \tau_{t-1}\right]^2 + \mathcal{O}(||\xi||^3).
\]

The steady-state value of \( \Delta_w \) is thus

\[
\Delta_w = \frac{\alpha_w}{(1 - \alpha_w)^2} [(1 - \gamma_z) \mu_z + (1 - \gamma_w) \tau_t]^2
\]

58
We obtain finally
\[
\Delta_{w,t} = \alpha_w \Delta_{w,t-1} + \frac{\alpha_w}{1 - \alpha_w} \left[ (1 - \gamma_z) \mu_z + (1 - \gamma_w) \pi + \hat{\pi}_{w,t} - \gamma_w \hat{\pi}_{t-1} \right] - \frac{1 - \theta_w}{2} Q_{1,w}(\Delta_{w,t} - \Delta_{w,t-1})^2 + O(||\zeta||^3).
\]

Here, treating \( \pi \) as an expansion parameter will not suffice to ensure that wage dispersion \( \Delta_{w,t} \) is second order because an additional constant term linked to average productivity shows up in the above equations. Henceforth, we will assume that \( \mu_z \) is an expansion parameter.

Then, if we treat \( \pi \) as an expansion variable, precisely because the steady-state value of \( \Delta_p \) is of second-order, many of the expressions previously derived considerably simplify. In particular, we now obtain
\[
p_{t} = \bar{p}_{t} + \frac{1 - \theta_p}{2} \Delta_{p,t} + O(||\zeta, \pi||^3),
\]
\[
w_{t} = \bar{w}_{t} + \frac{1 - \theta_w}{2} \Delta_{w,t} + O(||\zeta, \pi||^3).
\]

Now, because \( \Delta_y \) and \( \Delta_n \) are proportional to \( \Delta_p \) and \( \Delta_w \), respectively, and because \( \Delta_p \) and \( \Delta_w \) are both proportional to \( \pi^2 \), we also obtain
\[
\bar{n}_{t} = \mathbb{E}_{h}\{\bar{n}_{t}(h)\} + \frac{1 - \theta_w}{2} \Delta_{h,t} + O(||\zeta, \pi||^3),
\]
\[
\bar{n}_{t} = \phi(\mathbb{E}_{f}\{\bar{g}_{z,t}(f)\} - z_t) + \frac{1}{2} \phi^2 \Delta_{y,t} + O(||\zeta, \pi||^3),
\]
\[
\bar{g}_{t} = \mathbb{E}_{f}\{\bar{g}_{t}(f)\} + \frac{1 - \theta_p}{2} \Delta_{y,t} + O(||\zeta, \pi||^3).
\]

Thus, for sufficiently small inflation rates, we obtain formulas resembling those derived in Woodford (2003).

Finally, price and wage dispersions rewrite
\[
\Delta_{p,t} = \alpha_p \Delta_{p,t-1} + \frac{\alpha_p}{1 - \alpha_p} \left[ (1 - \gamma_p) \pi + \hat{\pi}_t - \gamma_p \hat{\pi}_{t-1} \right] + O(||\zeta, \pi||^3),
\]
\[
\Delta_{w,t} = \alpha_w \Delta_{w,t-1} + \frac{\alpha_w}{1 - \alpha_w} \left[ (1 - \gamma_z) \mu_z + (1 - \gamma_w) \pi + \hat{\pi}_{w,t} - \gamma_w \hat{\pi}_{t-1} \right] + O(||\zeta, \pi||^3).
\]

### J.5 Combining the Results

Combining the previous results, we obtain
\[
\int_0^1 \frac{\chi}{1 + v} e^{\xi_h} (N_h(h))^{1+v} dh = \chi(N^n)^{1+v} \left[ \bar{n}_t + \frac{1}{2} (1 + v) \bar{\pi}_t^2 + \bar{n}_t \bar{\pi}_h \right]
\]
\[
+ \frac{1}{2} (1 + v \theta_w) \theta_w \Delta_{w,t} + t.i.p + O(||\zeta, \pi||^3).
\]

59
In turn, we have
\[ \bar{n}_t = \phi \bar{y}_t + \frac{1}{2} \phi [(\phi - 1) \theta_p + 1] \theta_p \Delta_p,t + \mathcal{O}(||\zeta||^3), \]
so that
\[ \int_0^1 \frac{X}{1 + v} e^{\xi h,t} (N_t(h))^{1+v} \, dh = \phi \chi (N^p) \frac{1}{1 + v} \left[ (\bar{y}_t - z_t) + \frac{1}{2} (1 + v) \phi \bar{y}_t^2 + \bar{y}_t \xi_{h,t} \right] + \frac{1}{2} [(\phi - 1) \theta_p + 1] \theta_p \Delta_p,t + \frac{1}{2} (1 + v \theta_w) \phi^{-1} \theta_w \Delta_w,t \] + t.i.p + \mathcal{O}(||\zeta||^3), \}

Then, using
\[ (1 - \Phi) \frac{1 - \beta \eta}{1 - \eta} = \phi \chi (N^p) \frac{1}{1 + v}, \]
where we defined
\[ 1 - \Phi = \frac{1 + \tau_w 1 + \tau_p}{\mu_w \mu_p}, \]
we obtain
\[ \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left\{ \int_0^1 \frac{X}{1 + v} e^{\xi h,t} (N_t(h))^{1+v} \, dh \right\} = \]
\[ (1 - \Phi) \frac{1 - \beta \eta}{1 - \eta} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ \bar{y}_t + \frac{1}{2} (1 + v) \phi \bar{y}_t^2 + \bar{y}_t \xi_{h,t} \right] + \frac{1}{2} [(\phi - 1) \theta_p + 1] \theta_p \Delta_p,t + \frac{1}{2} (1 + v \theta_w) \phi^{-1} \theta_w \Delta_w,t \] + t.i.p + \mathcal{O}(||\zeta||^3), \}

Assuming the distortions are themselves negligible, this simplifies further to
\[ \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left\{ \int_0^1 \frac{X}{1 + v} e^{\xi h,t} (N_t(h))^{1+v} \, dh \right\} = \]
\[ \frac{1 - \beta \eta}{1 - \eta} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ (1 - \Phi) \bar{y}_t + \frac{1}{2} (1 + v) \phi \bar{y}_t^2 + \bar{y}_t \xi_{h,t} \right] + \frac{1}{2} [(\phi - 1) \theta_p + 1] \theta_p \Delta_p,t + \frac{1}{2} (1 + v \theta_w) \phi^{-1} \theta_w \Delta_w,t \] + t.i.p + \mathcal{O}(||\zeta||^3), \}

We now deal with the first term in the utility function. To that end, notice that
\[ \sum_{t=0}^{\infty} \beta^t a_{t-1} = a_{-1} + \beta \sum_{t=0}^{\infty} \beta^{t-1} a_{t-1} = a_{-1} + \beta \sum_{t=0}^{\infty} \beta^t a_t. \]

Using this trick, we obtain
\[ \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t e^{\xi h,t} \log (C_{z,t} - \eta C_{z,t-1} e^{-\frac{\xi h,t}{\tau}}) = \frac{1 - \beta \eta}{1 - \eta} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ g_{z,t} - \frac{1}{2} [\phi (1 + \beta \eta^2) - 1] g_{z,t}^2 + \eta \phi g_{z,t} \bar{y}_{z,t-1} \right] + \phi \hat{g}_{z,t} \bar{y}_{z,t} - \eta \phi \xi_{z,t} g_{z,t} + \text{t.i.p} + \mathcal{O}(||\zeta||^3), \]

60
where we defined
\[ \varphi^{-1} = (1 - \beta \eta)(1 - \eta), \]

\[ \hat{\xi}_t = (1 - \eta)(\zeta_{c,t} - \beta \eta \mathbb{E}_t\{\zeta_{c,t+1}\}), \]

so that

\[ (1 - \beta \eta)\varphi \hat{\xi}_t \equiv (\zeta_{c,t} - \beta \eta \mathbb{E}_t\{\zeta_{c,t+1}\}). \]

and

\[ \zeta^*_t = \zeta_{z,t} - \beta \mathbb{E}_t\{\zeta_{z,t+1}\} \]

Combining terms, we obtain

\[
U_0 = \frac{1 - \beta \eta}{1 - \eta} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ \Phi \bar{y}_{z,t} - \frac{1}{2} \varphi(1 + \beta \eta^2) + \omega\right] \bar{y}_{z,t} + \eta \varphi \bar{y}_{z,t} \bar{y}_{z,t-1} + (\varphi \hat{\xi}_t - \hat{\xi}_{h,t} - \varphi \eta \hat{\xi}^*_t) \bar{y}_{z,t} - \frac{1}{2} (\varphi(1 + \theta_p + 1)\varphi \Delta_{p,t} - \frac{1}{2} (1 + v \theta_w) \varphi^{-1} \varphi \Delta_{w,t}) + t.i.p + O(||\xi||^3),
\]

where, as defined earlier

\[ \omega = (1 + v) \varphi - 1 \]

Now, recall that

\[
[\varphi(1 + \beta \eta^2) + \omega]\bar{y}_{z,t} - \varphi \beta \eta \mathbb{E}_t\{\bar{y}_{z,t+1}\} - \varphi \eta \bar{y}_{z,t-1} = \varphi \hat{\xi}_t - \hat{\xi}_{h,t} - \varphi \eta \hat{\xi}^*_t = \bar{y}_{t}. \]

Using this above yields

\[
U_0 = \frac{1 - \beta \eta}{1 - \eta} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ \Phi \bar{y}_t - \frac{1}{2} \varphi(1 + \beta \eta^2) + \omega\right] \bar{y}_t + \eta \varphi \bar{y}_t \bar{y}_{t-1} + \varphi \Delta_{p,t} - \frac{1}{2} (1 + v \theta_w) \varphi^{-1} \varphi \Delta_{w,t}) + t.i.p + O(||\xi||^3),
\]

\[
U_0 = \frac{1 - \beta \eta}{1 - \eta} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ \Phi \bar{y}_t - \frac{1}{2} \varphi(1 + \beta \eta^2) + \omega \right] \bar{y}_t + \eta \varphi \bar{y}_t \bar{y}_{t-1} + \varphi \Delta_{p,t} - \frac{1}{2} (1 + v \theta_w) \varphi^{-1} \varphi \Delta_{w,t}) + t.i.p + O(||\xi||^3).
\]
To simplify this expression, we seek constant terms \( \delta_0, \delta \) and \( x^* \) such that

\[
\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left\{ -\frac{1}{2} \delta_0 [(\check{y}_t - \hat{y}^n_t) - \delta (\check{y}_{t-1} - \hat{y}^n_{t-1}) - x^*]^2 \right\} = \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[ \Phi \check{y}_t - \frac{1}{2} (\varphi + \beta \eta^2) \hat{y}^2_t + \eta \varphi \check{y}_t \check{y}_{t-1} + [\varphi + \beta \eta^2] \check{y}_t \hat{y}^n_{t+1} - \varphi \eta \check{y}_t \hat{y}^n_{t-1} \right] + \text{t.i.p}
\]

Developing yields

\[
- \frac{\delta_0}{2} [(\check{y}_t - \hat{y}^n_t) - \delta (\check{y}_{t-1} - \hat{y}^n_{t-1}) - x^*]^2 = -\frac{1}{2} \delta_0 \check{y}^2_t + \delta_0 \check{y}_t \hat{y}^n_t + \delta_0 \delta \check{y}_t \check{y}_{t-1} - \delta_0 \delta \check{y}_t \hat{y}^n_{t-1} - \delta_0 \delta \check{y}_{t-1} \hat{y}^n_t - \frac{1}{2} \delta_0 \delta^2 \hat{y}^2_{t-1} + \delta_0 \delta^2 \check{y}_{t-1} \hat{y}^n_{t+1} + \delta_0 (\check{y}_t - \delta \check{y}_{t-1}) \check{x}^* + \text{t.i.p}
\]

Thus

\[
\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left\{ -\frac{\delta_0}{2} [(\check{y}_t - \hat{y}^n_t) - \delta (\check{y}_{t-1} - \hat{y}^n_{t-1}) - x^*]^2 \right\} = \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left\{ \delta_0 (1 - \beta \delta) \check{x}^* \check{y}_t - \frac{1}{2} \delta_0 (1 + \beta \delta^2) \check{y}^2_t + \delta_0 \delta \check{y}_t \check{y}_{t-1} + \delta_0 (1 + \beta \delta^2) \check{y}_t \hat{y}^n_{t+1} - \delta_0 \delta \check{y}_t \hat{y}^n_{t-1} - \delta_0 \delta \check{y}_{t-1} \hat{y}^n_t \right\} + \text{t.i.p}
\]

Identifying term by term, we obtain

\[
\delta_0 (1 - \beta \delta) \check{x}^* = \Phi
\]

\[
\delta_0 (1 + \beta \delta^2) = [\varphi + \beta \eta^2]
\]

\[
\delta_0 \delta = \eta \varphi
\]

Combining these relations, we obtain

\[
\eta \delta^2 - \frac{\varphi + \beta \eta^2}{\beta \varphi} \delta + \eta \beta^{-1} = 0,
\]

or equivalently

\[
\mathbb{P}(\kappa) = \beta^{-1} \kappa^2 - \chi \kappa + \eta^2 = 0,
\]

where

\[
\kappa = \frac{\eta}{\delta},
\]

62
\[ \chi = \frac{\omega + \phi (1 + \beta \eta^2)}{\beta \phi} > 0. \]

Notice that
\[ P(0) = \eta^2 > 0, \]
\[ P(1) = -\frac{\omega}{\beta \phi} < 0 \]
so that the two roots of \( P(\kappa) = 0 \) obey
\[ 0 < \kappa_1 < 1 < \kappa_2. \]

In the sequel, we focus on the larger root and define
\[ \kappa = \kappa_2 = \frac{\beta}{2} \left( \chi + \sqrt{\chi^2 - 4 \eta^2 \beta^{-1}} \right) > 1. \]

Since \( \delta = \eta / \kappa \), we have
\[ 0 \leq \delta \leq \eta < 1. \]

Thus, given the obtained value for \( \kappa \), we can deduce \( \delta \) from which we can compute \( \delta_0 \).

We thus obtain
\[ U_0 = -\frac{1 - \beta \eta}{1 - \eta} \mathbb{E} \sum_{t=0}^{\infty} \beta^t \delta_0 \left\{ \frac{\delta_0}{2} \left[ (\hat{y}_t - \hat{y}_t^0) - \delta(\hat{y}_{t-1} - \hat{y}_{t-1}^0) - \chi^* \right]^2 \right. + \frac{1}{2} [(\phi - 1) \theta_p + 1] \theta_p \Delta_{p,t} + \frac{1}{2} (1 + \nu \theta_w) \phi^{-1} \theta_w \Delta_{w,t} \right\} + t.i.p + O(||\zeta, \pi||^3), \]

The last step consists in expressing price and wage dispersions in terms of squared price and wage inflations.

Recall that
\[ \Delta_{p,t} = \alpha_p \Delta_{p,t-1} + \frac{\alpha_p}{1 - \alpha_p} \left[ (1 - \gamma_p) \pi + \hat{\pi}_t - \gamma_p \hat{\pi}_{t-1} \right]^2 + O(||\zeta, \pi||^3), \]

Iterating backward on this formula yields
\[ \Delta_{p,t} = \frac{\alpha_p}{1 - \alpha_p} \sum_{s=0}^{t} \alpha_p^{-s} \left[ (1 - \gamma_p) \pi + \hat{\pi}_s - \gamma_p \hat{\pi}_{s-1} \right]^2 + t.i.p + O(||\zeta, \pi||^3), \]

It follows that
\[ \sum_{t=0}^{\infty} \beta^t \Delta_{p,t} = \frac{\alpha_p}{(1 - \alpha_p)(1 - \beta \alpha_p)} \sum_{t=0}^{\infty} \beta^t \left[ (1 - \gamma_p) \pi + \hat{\pi}_t - \gamma_p \hat{\pi}_{t-1} \right]^2 + t.i.p + O(||\zeta, \pi||^3), \]

and by the same line of reasoning
\[ \sum_{t=0}^{\infty} \beta^t \Delta_{w,t} = \frac{\alpha_w}{(1 - \alpha_w)(1 - \beta \alpha_w)} \sum_{t=0}^{\infty} \beta^t \left[ (1 - \gamma_w) \mu_z + (1 - \gamma_w) \pi + \hat{\pi}_{w,t} - \gamma_w \hat{\pi}_{t-1} \right]^2 + t.i.p + O(||\zeta, \pi||^3), \]
Thus, defining

\[ \lambda_y \equiv \delta_0 \]

\[ \lambda_p \equiv \frac{\alpha_p \theta_p [(\phi - 1)\theta_p + 1]}{(1 - \alpha_p)(1 - \beta \alpha_p)} \]

\[ \lambda_w \equiv \frac{\alpha_w \phi^{-1} \theta_w (1 + \nu \theta_w)}{(1 - \alpha_w)(1 - \beta \alpha_w)} \]

The second order approximations to welfare rewrites

\[ U_0 = -\frac{1}{2} \frac{1 - \beta \eta}{1 - \eta} E_0 \sum_{t=0}^{\infty} \beta^t \left\{ \lambda_y [x_t - \delta x_{t-1} + (1 - \delta) \bar{x} - \bar{x}^*]^2 + \lambda_p [(1 - \gamma_p) \pi + \hat{\pi}_t - \gamma_p \hat{\pi}_{t-1}]^2 \right. \]

\[ + \left. \lambda_w [(1 - \gamma_z) \mu_z + (1 - \gamma_w) \pi + \hat{\pi}_{w,t} - \gamma_w \hat{\pi}_{t-1}]^2 \right\} + \text{i.p} + \mathcal{O}(||\zeta, \pi||^3), \]

where we defined

\[ x_t \equiv \hat{y}_t - \hat{y}_t^n \]

\[ \bar{x} \equiv \log \left( \frac{Y_z}{Y_z^n} \right). \]
